AT a stated meeting of this society, held March 17th, DR. GEORGE L. PEABODY read a paper on the treatment of typhoid fever, which was mainly devoted to a plea for the more general use of the full cold bath in this disease. As the prophylactic treatment of typhoid fever had been so fully and ably set forth in the recent paper of Dr. Janeway before the Association, he said he would confine himself to a consideration of the treatment of a few of the more important symptoms. As a disinfectant for the stools of patients and for general use in the sick room, he thought the best and

cheapest article was a solution of corrosive sublimate. It had been proved that the stools were not infectious immediately after being passed, and it was not known at precisely what period they became so; but experience had shown that after the lapse of twelve hours, at all events, they were infectious. It was also uncertain for how long a period they retained this character, but in one instance on record some workmen were taken down with typhoid fever after overturning a dung-heap under which the stools of typhoid-fever patients had been placed two years before. There was one point which was not, perhaps, sufficiently insisted upon, and that was the importance of disinfecting the contents of the intestines before throwing them into the sewer when making autopsies in the case of those who had died from typhoid fever.

One essential point in the proper treatment of this disease was that the patient should be put to bed at a very early period, and kept there until convalescence had become fully established. The importance of this matter was abundantly illustrated in the history of many hospital patients who were placed under treatment at a comparatively late period, and in whose cases in consequence the results were unsatisfactory. The bad results of late treatment were particularly well shown in the reports of St. Bartholomew's Hospital for the year 1882. After speaking of the desirability of a roomy and well-ventilated chamber, with two beds for the use of the patient, and of the greater mortality of the disease in summer than at any other season, in consequence of the higher temperature to which the patient was exposed, Dr. Peabody went on to say that it was well to humor the sick in small things as far as possible, and very important in case delirium was present that they should be gently soothed, and not forcibly restrained. Having alluded to Liebermeister's plan of administering calomel, and to the continued and systematic use of a weak solution of iodine, which, it had been claimed, materially lessened the mortality from the disease, but with which he had had no personal experience, he went on to relate the case of a willful and spoiled child in which practically no treatment was carried out, and yet in which complete recovery resulted. The temperature varied between 102.5° F. and 104.5° F. The marked impairment in digestion which was so common in typhoid fever he thought was due in some measure to the absence of saliva, so that he would advise the application of vaseline to the lips from time to time, as well as quite a free use of water. In the way of diet the main reliance was to be placed on milk, whether peptonized or not, and the patient would do well if two quarts could be taken in the twenty-four hours. Animal broths were also of service in supporting the action of the heart and the central nervous system, and in some cases rectal alimentation was called for. In regard to the use of spirits he said that they should be given early only in the case of drunkards or those habitually accustomed to alcohol. Many cases would do perfectly well throughout without any at all, but frequently they were of very great service in the later stages of the disease. In New York at the present time he thought the tendency was to resort to their use rather too early. In every case the physician was to be guided by the indications present, and in some instances it would be found that nearly a quart of spirits in the twenty-four hours would be required.

As the disease subsided he thought it was desirable to allow the use of solid food. If the proper kind of food was employed he believed there was no danger whatever in the practice, and the often-repeated assertion that an early return to solid food was accompanied by a tendency to relapse was not borne out by experience. After the intestinal ulcerations were covered with granulations the risk of perforation and hæmorrhage, he thought, was past. The muscular twitching which had been so much spoken of as a sign of ulceration did not indicate this at all. He thought it advisable that the patient should have a little meat as soon as the fever subsided, this being a food which could be digested entirely in the stomach, which was a desirable consideration in the first solid food employed. He had had no experience with the use of beef peptones.

As a rule the medical attendant's chief aim was to ward off the evil effects of long-continued high temperature. Serious parenchymatous alterations inevitably resulted from this, and Dr. Peabody's experience showed that no typhoid fever patient ever reached the third week of the disease without the occurrence of more or less granulo-fatty degeneration of the walls of the heart. The kidneys, liver, and other organs were also liable to be similarly affected, and in some instances waxy degeneration of the organs resulted. Dr. Cayley, in the Croonian Lectures for 1880, had expressed the opinion that the majority of deaths in typhoid fever were due to failure of the heart and central nervous system with resultant congestion of the lungs. The clinical indications of these parenchymatous changes incident to a long-continued high temperature had been clearly pointed out by Lauder Brunton. In order to show the superiority of the method of treatment by cold-water baths Dr. Peabody said he would first quote some statistics of cases treated under the old expectant plan. In the London Fever Hospital there were treated, during twenty years, 8000 typhoid-fever patients, with a mortality of 18.9 per cent.; at St. George's Hospital, 387 cases, with a mortality of 19.6 per cent.; at Guy's Hospital, 295, with a mortality of 19.3 per cent.; at University College Hospital, 167 cases, with a mortality of 17.7 per cent.; and at St. Bartholomew's Hospital, 635 cases, with a mortality of 16.3 per cent. At St. Thomas's Hospital the mortality amounted to 15.7 per cent., and at King's College Hospital to 12.2 per cent. In all there were 14,125 cases, with an average mortality of 17.8 per cent. At Vienna 17,000 cases were treated, with a mortality of 22.5 per cent., and at Basle, Switzerland, the mortality was 27.3 per cent. In the English army, during the six years ending with 1877, the mortality in cases of typhoid fever among the home troops averaged 24 per cent., and among the foreign troops, 40.7 per cent. In the English navy, during the six years ending with 1878, there were 414 cases of typhoid fever, with 110 deaths, a mortality of 26.5 per cent. In the United States army, during the late war, there were, among the white troops, 75,368 cases of typhoid fever, with 26,981 deaths, a mortality of 35.8 per cent., and among the negro troops 4500 cases, with 2280 deaths, a mortality of 55.6 per cent. After quoting the statistics of typhoid fever in the principal hospitals of New York, as given in the recent paper on this subject read by Dr. Francis Delafield before the Academy of Medicine, Dr. Peabody went on to say that we certainly could not be satisfied with the expectant plan of treatment unless we thought, with Skoda, that it made no difference whether typhoid fever was treated or not.

Then having spoken of the labors of John Curry in the latter part of the last century in connection with the external use of cold water in fevers, and the recent revival of the practice by Brandt, of Stetin, he proceeded to give some statistics showing the decreased mortality since the cold bathing had come into use. At the Berlin Hospital from 1848 to 1867 there were treated 2228 cases of typhoid fever, with a mortality of eighteen per cent.; while from 1868 to 1881 there were 2000 cases and 267 deaths, a mortality of thirteen per cent. If from the number of fatal cases there were deducted sixty-four which died very shortly after admission, the mortality was only 10.5 per cent. In the Prussian army the mortality among typhoid fever patients from 1868 to 1874 amounted to fifteen per cent.; while during the last seven years, when the antipyretic treatment was practiced, it was only 9.7 per cent. At Basle the mortality had been reduced from 27.3 to 8.8 per cent., at Kiel from 15.4 to 3.1 per cent., and at Stetin from 25.6 to four per cent. Brandt had reported no less than 211 successive cases without a single death. Brandt's rule was to commence the full cold bath (the temperature of the water being at from 67° F. to 70° F.) as soon as the patient's temperature, taken in the rectum, went up to 102.2° F., and Dr. Peabody thought that the adoption of this practice could not be too strongly urged. At the New York Hospital he had had a rubber bath-tub placed on wheels for use in the wards, and his own results had been quite satisfactory, although his experience was limited. He had found the cold bath useful not only in reducing the temperature but in relieving stupor, insomnia, and failure of the heart's action, and in one instance he had seen well-marked pulmonary œdema dissipated like magic by it. There was, perhaps, a greater tendency to relapse when the cold bath was used, but the relapses were not often of a serious character. It was contraindicated when there was intestinal hæmorrhage, aphonia from ulceration of the glottis, and venous congestion from chronic bronchitis or emphysema. Cold sponging in many cases, he believed, was wholly inefficient in reducing the temperature. As to the use of drugs for this purpose, he was not an advocate of the measure, since he believed that the large and frequently repeated doses of such agents as quinine, kairin, and salicylic acid which were required would have an injurious effect upon the patient if maintained for any length of time. In regard to the various complications of typhoid fever he said that he would not have time to speak, but he was convinced that they would very rarely occur in cases where the patient was systematically subjected to the cold water bath.

DR. A. FLINT, JR., advocated, on theoretical grounds, the administration of fatty substances (such as cream and cod-liver oil), farinaceous articles, alcohol, and saccharine matters, especially glucose. After speaking at some length on the causation of animal heat, and expressing the opinion (derived particularly from experiments on the pedestrian, Weston, and on his own person) that the formation of water in the body from the union of oxygen and hydrogen was a most important factor in its production, he went on to say that in fevers there was an exaggeration of the normal process Since the fever fed on the tissues of the body, it followed that these tissues must suffer very greatly unless some other fuel could be furnished to feed the flames, and the question arose, how could this be supplied? The answer, he thought, was found in the administration to the patient of the class of articles of diet which have been mentioned, and in regard to alcohol, at least, it was already well known, he said, that the temperature in fevers was reduced by it.

The President, DR. DETMOLD, remarked that in proposing, as a physiologist, to administer these hydrocarbons to typhoid-fever patients, Dr. Flint forgot that simply introducing them into the alimentary canal did not introduce them into the tissues. He had presupposed normal digestion, while in this disease, as was well known, digestion, assimilation, and nutrition were very greatly impaired, and, consequently, the fuel which was designed to feed the flames of the fever would lie inert in the intestinal tract and be discharged inert from it.

DR. E. G. JANEWAY said he feared that an erroneous impression might be derived from the statistics which Dr. Peabody had quoted in support of the advantages of the refrigeration treatment, since in Europe it was the practice to leave out of such statistics the records of all cases which proved fatal within a few hours after admission to the hospital; while this was not the case in this country. Again, in considering the high death-rate noted in the United States army, it was worthy of note that many of the cases were transported for a very long distance; it being a very common thing to bring patients in the second and third week of the disease all the way from Virginia to New York. Such circumstances as these ought always to be taken into consideration in the study of hospital statistics. Still another point. Liebermeister and others in their statistics made no reference whatever to the age of patients, while age, it was not to be forgotten, made an extremely great difference in the rate of mortality from typhoid fever. In the young the result was almost invariably favorable, but in the old, and, indeed, in all persons above the age of twenty, the disease was very much more serious. In the Mount Sinai Hospital, in which it had been noted by Dr. Peabody that the mortality was the smallest of any of the New York hospitals, the comparatively low death-rate was due, he believed, to the fact, which he had ascertained, that an unusually large proportion of children with the disease had been treated there. During an outbreak of typhoid fever a number of years ago at the Deaf and Dumb Asylum, he had treated fifty cases with only two deaths, a mortality of four per cent., and in another institution he had obtained about the same results. In these instances the small mortality was due, not to the treatment adopted, but to the fact that the disease prevailed among young subjects. At the same time he was himself a believer in the antipyretic treatment, though he thought that the mode of applying the cold water should be modified according to the circumstances and character of each particular case. In the division of Bellevue Hospital to which both he and Professor Flint were attached this had been the practice for a number of years. Dr. Janeway concluded with a few remarks on the subject of diet, in the course of which he said that he thought that the return to the use of solid food should be made with great care.

DR. A. FLINT, SR., said that there was only one point, and that not a very important one, in regard to which he differed from the author of the paper. This was as to the value of cold sponging. His observation had led him to believe that if properly carried out it was a very efficient method of reducing temperature,

though if it was not thoroughly performed it was of little use. He had also gone through the experience of Dr. Peabody with a portable bath-tub, but he had found the method extremely inconvenient, and also that, as a rule, all the advantages of the full bath could be obtained by sponging. In any case where sponging did not reduce the temperature as completely as was desired the end, he felt certain, could be attained by the use of the cold pack, the patient being wrapped in a sheet and kept thoroughly sprinkled. For several years he had pursued this plan with advantage in Bellevue Hospital, and consequently had long since dispensed with the cumbersome bath-tub. He agreed with Dr. Peabody in regard to the desirability of an early resort to the use of solid food, and thought that it was a good rule to allow the patient to have it as soon as he felt a desire for it. He did not believe that there was any specific for typhoid fever, and thought that each case ought to be treated according to the special characteristics which it manifested. In regard to the administration of alcohol, he said that he had passed through three different phases of opinion on the subject. When he first commenced the practice of medicine it was customary to starve fever patients as far as possible, and no alcohol whatever was allowed. Afterwards medical opinion went to the opposite extreme, and alcohol was given to excess, but still more recently there seemed to be a tendency, he thought, not to appreciate the advantages of the free use of alcohol in appropriate cases.

In bringing the discussion to a close Dr. Peabody said that there was an additional objection to the suggestion of Dr. Flint, Jr., and that was the difficulty that there would be in getting typhoid-fever patients to take sweet or greasy substances, since it was well known how hard it was to secure the taking of sufficient nourishment of a kind that was more agreeable to the sick. After replying to the criticisms of Dr. Janeway he remarked, in conclusion, that he did not doubt the efficacy of cold sponging if it was properly carried out, but the trouble was, according to his observation, that this was *not* done practically, as a rule, and hence he was still inclined to urge the use of the full cold bath as the most efficient means of reducing temperature in the average case of typhoid fever.

RHODE ISLAND MEDICAL SOCIETY.

QUARTERLY MEETING.

March 20, 1884. Lyceum Hall, Providence.

Dr. N. O'D. Parks read a paper on

TOPICAL CARDIAC BLISTERING IN THE TREATMENT OF ACUTE RHEUMATISM,

and recited several illustrative cases.

Case I. Mr. B. was treated for acute rheumatism by the administration of salicin, in scruple doses, with five grains of ammonia carbonate every three hours. Under this treatment he rapidly improved, and in ten days appeared to be convalescent, and resumed his ordinary pursuits. In a few days, however, a relapse was threatened, indicated by pain and swelling of the knee and tarsal joints and an endocardial murmur. A blister, five by six inches, was applied over the heart, with the happy effect of aborting the threatened relapse, all symptoms of which, including the endocardial murmur, quickly disappeared. Urine and saliva became alkaline. No return of the malady.

Case II. An old lady who, every winter, is a victim to so-called "rheumatic gout," which usually attacks each great toe in succession. On this occasion most of the joints of each foot and some joints of the upper extremities, including the metacarpo-phalangeal and phalangeal joints of both hands, were involved, with the usual accompaniment of great pain, swelling, and high fever. A blister was ordered over the heart, and the affected joints anointed with ol. gaultheriæ, which was also exhibited internally, in fifteen-drop doses, every two hours. In three days she was able to sit up, and in less than a fortnight was out driving in her buggy, handling the reins herself. No symptom of relapse.

Case III. Mrs. M., aged forty. Right toe and ankle-joints swollen and painful. Urine and saliva highly acid. Ordered ten grains of salicin and two and a half grains of ammonia carbonate, to be repeated hourly. Fly blister, four by five inches, over the heart. On the next day the left foot was attacked. Ordered salicin, fifteen grains, and ammonia carbonate, five grains, every two hours. Dressed the blistered surface with unguentum sabinæ. She did well for five days, when the right instep became swollen and painful. Blister over the heart repeated. The following day she felt much better. No pain. From this time convalescence was uninterrupted.

The history of several similar cases of acute rheumatism was given, the cure in each case being rapid and complete. The writer had tried all the modern methods of treating rheumatism, but none yielded such satisfactory results as followed the action of a blister over the heart combined with the administration of salicin or some of the salicyl compounds.

Dr. Ariel Ballou had suffered from three attacks of rheumatic fever, and had found that a blister over the heart gave relief when the fever threatened to be high. He recommended the opium treatment in muscular rheumatism, as in his experience it tended to prevent a metastasis of the disease to the heart. The treatment of this disease has hitherto been largely empirical. The speaker had gathered eighty "sure cures" for rheumatism.

Dr. Herbert Terry read a paper on

THE TREATMENT OF PUERPERAL FEVER,

founded on personal observation of eleven cases. The prevention of puerperal fever was briefly discussed. One of the most valuable prophylactic measures yet advocated is the production of a firm and continuous contraction of the uterus after the placenta is expelled. Ergot should be given in every case as soon as the after-birth is delivered, and for half an hour, at least, the hand should remain over the uterus, and any relaxation should be met by gently rubbing the uterus, cold to the abdomen, etc. After tonic contraction of the uterus is insured, and the patient thoroughly cleansed, a firm binder should be applied from the ensiform cartilage to the pubes. Ergot should be continued in smaller doses at least until the color has left the lochia.

Against vaginal douches during labor there is at least one theoretical objection. They wash away the mucus secreted during labor to aid in the passage of the head. A single injection, however, as labor begins may be advantageous.

Vaginal douches after confinement are unnecessary unless the lochia are offensive, — and then only for the

sake of cleanliness. More attention might well be paid to the condition of the napkin, as offensive discharges appear to be often due to retaining a soiled napkin. In this connection favorable reference was made to Dr. Garrigues' recent paper advocating the use of a bandage composed of lint wrung out of a one to two thousand solution of bichloride of mercury and covered with oiled muslin. Three times a day the bandage is renewed and genitals washed.

The indications for treatment in puerperal septicæmia are to keep the patient alive until the morbid process ends, and also to prevent any further absorption. For the latter purpose antiseptic intra-uterine douches are the most effectual means. When in doubt as to whether the disease is puerperal fever or milk fever, or as to the location of the point of absorption, it is a good rule to wash out the uterus without delay. If carefully done, the intra-uterine douche is as safe as the vaginal injection. The Davidson was preferred to the fountain syringe, because the direction and force of the stream are under more perfect control. The choice of a tube has to do with some of the dangers alleged against this treatment. It should be large enough to avoid entering a sinus or the Fallopian tubes, yet should not block up the os, and should be about twice the length of the ordinary vaginal nozzle. Some of the tubes used for this purpose are closed at the end, with several openings in the side directed outward and backward so that not only is the force of the stream diminished but it always flows towards the mouth of the womb. It seems important, however, that the fundus of the uterus as well as other portions should be well washed, and, to accomplish this, the hole in the end of the tube should be retained. As to antiseptics, carbolic acid may be employed in a strength of one to sixty, or even one to forty. A permaganate of potash solution of four grains to the ounce is valuable. Corrosive sublimate may be used in a solution of one to two thousand.

Alcohol, opium, quinine, digitalis, and the bromides are invaluable; but without the use of some germicide intra-uterine wash they do not promptly reduce the temperature or shorten the disease.

DR. H. G. MILLER read a brief paper on

BLEPHAROSPASM.

Although usually divided into three stages according to its degree, four varieties may more properly be recognized. The first is one of the slightest and least significant of the eye troubles for which patients seek advice. A simple spasmodic contraction of a few fibres of either the upper or lower portion of the orbicularis, and which the patient often refers to the eye-ball itself. It seems to occur most frequently in near-sighted persons.

The second form, nictitation, affects the muscles of both sides at the same time and consists in too frequent or too violent winking. This is most common in children, and is frequently thought to be a manifestation of chorea. Oftenest caused by hyperæmia of the lids or chronic papillary conjunctivitis. It seems to be frequently a reflex expression of fatigue, either of the eyes themselves or of some other portion of the organism. The excessive use of tea, coffee, and tobacco not unfrequently seem to be the exciting cause.

The third form is an exaggeration of the natural effort of the lids to protect the eyes from external injury. Photophobia, whether from hyperæsthesia of the retina or more commonly from conjunctival and corneal affections, is the most common cause of this form. What at first is a mere voluntary or instinctive effort to shield the eye from harm becomes a spasmodic contraction of surprising force and indefinite duration. It even aggravates and increases the original disease, as well as interferes seriously with its proper treatment. The practiced fingers of the surgeon can almost always successfully cope with it; but to the friends to whom the details of treatment must generally be confided it presents an almost insuperable obstacle. Even when the diseased condition causing it is cured, the palpebral opening for a longer or shorter period is left smaller and narrower than before.

The fourth form is spasm of the orbicularis, usually on one side only, clonic in its character, sometimes uncomplicated but often extending to all the muscles supplied by the facialis. In its slighter degrees, occurring frequently during conversation, it gives the patient the appearance of voluntarily adding a mysterious significance to his words, often mortifying to those so affected. In a higher degree the whole side of the face is drawn and distorted. This form is sometimes associated with tic douloureux and adds terror to an already terrible malady. Unlike the other forms which are reflex in character, this one may be of central origin.

Cases were given illustrating each of the forms of the disease.

LOSS OF SIGHT FROM INJURY OF FACIAL NERVE.

DR. O'LEARY reported a case in which the sight of one eye was completely obliterated by injury of the facial nerve. The patient, while on picket duty, received a bullet wound over the eye, barely grazing the skin.

DR. MILLER thought the loss of sight was a reflex effect from shock of the facialis.

DR. W. J. BURGE reported a case of

MALIGNANT DISEASE OF THE BLADDER,

and DR. CASWELL exhibited the specimen. There had been symptoms of vesical calculus, for which he was sounded without detecting a stone, though he passed a small one soon after leaving Dr. Caswell's office. The evacuating tube and a current of water would probably detect a stone in such a case better than an ordinary searcher. There was entire suppression of urine for four days before death. The growth extended across the bladder so as to close both ureters. The right kidney was atrophied, and the left with its ureter dilated. The tumor had the appearance of fibro-sarcoma.

EXHIBITION OF VARIOUS SPECIMENS.

DR. CASWELL exhibited six small calculi weighing together twenty-five grains, which he removed from the roof of a urinary fistula. They seemed to have formed in the passage.

DR. KEMP, of Lonsdale, exhibited a specimen of Aneurism of the Aorta with Cardiac Hypertrophy.

DR. LLOYD MORTON reported a case of Oblique Fracture of the Femur through the trochanteric portion, and exhibited the specimen. There was only a ligamentous union, but the patient was able to walk.

DEATHS.

The President announced the death of DRS. T. W. PERRY and OTIS BULLOCK. A committee consisting

of Drs. W. E. Anthony, Ariel Ballou, and E. T. Caswell was appointed to prepare resolutions on the death of each of these venerable members.

ELECTION OF FELLOWS AND DELEGATES.

As recommended by the Board of Censors, Drs. George R. Smith, of Woonsocket, and William F. Morrison, of Providence, were elected Fellows.

Delegates to the annual meeting of the American Medical Association were elected as follows: —

Ariel Ballou, G. P. Baker, P. E. Bishop, G. A. Brug, Herman Canfield, A. C. Dedrick, J. H. Eldredge, J. W. C. Ely, C. H. Fisher, S. W. Francis, James Hanaford, G. H. Kenyon, J. H. Morgan, S. O. Myers, N. O'D. Parks, A. A. Saunders, H. W. Stillman, H. E. Turner, and A. E. Tyng.

Medical and Surgical Journal.

THURSDAY, MARCH 27, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

THE HYGIENE OF STUDY.

EX-SURGEON-GENERAL HAMMOND says that children should not be sent to school until they are ten or twelve years of age, ten at the earliest. Deferring for a moment the sanitary aspects of the question, the suggestion of Dr. Hammond as applicable to the great majority of children — those especially of mechanics, artisans, operatives who require the services of their children at an early age — would be impracticable. The Massachusetts law fixes the school age at from five to fifteen, and requires that all between those periods shall receive a certain number of weeks' instruction every year; every child *must* be in school for at least twenty weeks of the year from the time he is eight until he reaches the age of fourteen years. Among the wealthier classes, and those whose means enable them to give their children a longer term of education, there is less need of beginning school instruction till the organism is somewhat matured. As a question of the amount of learning which can be gained it is probable that it would not be much if at all diminished by retarding the time when children are sent to school. A healthy, bright boy of sixteen would get more from a book in a week than a child of six would in several months, and many parents who have kept their children from books until they were seven or eight years old have found that they have made progress in their studies rapid enough to compensate for the delay. In the earlier periods of life knowledge is chiefly gained, as in the earlier history of the race, by observation, and too rapid a stimulation of mental development is likely to be followed by arrest of cerebral growth. "The brain," says Herbert Spencer, "which during early years is relatively large in mass, but imperfect in structure, will, if required to perform its functions with undue activity, undergo a structural advance greater than is appropriate to the age; but the ultimate effect will be a falling short of the size and power that would else have been attained. And this is a part cause — probably the chief cause — why precocious children and youths who up to a certain time were carrying all before them so often stop short and disappoint the high hopes of their parents."

As regards the number of hours a day which may profitably be devoted to study there can be no fixed rule; age, temperament, sex, constitution, and state of health must be taken into account. Those of tender years, and children generally during the period of growth, are less able to bear prolonged mental application than vigorous adults; nor, as before said, is it desirable to develop the juvenile brain at the expense of other organs. Those of the sanguine and nervous temperaments (if we may use terms which are becoming somewhat obsolete) are more restive, and suffer more under the restraint necessitated by study than those of other temperaments, and (other things being equal) they learn faster, owing to predominance of the circulatory and nervous energies. Females, as a rule, are capable of less continuous study than males, and those of strong constitutions in both sexes may bear, not only with impunity, but with profit, an amount of prolonged mental work which to weakly persons might be disastrous and even fatal. The same remark may be made apropos of states of health; hard and continuous exercise of the brain demanding, in order to be truly efficient, a sound condition of the organism. The truth is obvious enough, though needing frequent inculcation, that vigor of the circulation and integrity of the nutritive and other functions — a condition, in fact, of general *bien être* attended with a flow of spirits and absence of fatigue — should accompany the endeavors of the student, being essential to the successful grasp and assimilation of knowledge, while corporal inactivity, an enfeebled circulation, even a disordered viscus, entail depression or inhibition on the noblest of the cerebral activities.

To say then how much of the diurnal cycle should be devoted to study demands a knowledge of individual constitutions and capacities, and a decision can be arrived at only by an examination of particular cases. Here parents and teachers are called upon to exercise careful judgment. For the majority of children the ordinary five or six hours of daily schooling, with their recesses and interruptions, are probably not too much. Nor must it be taken for granted that these school hours are characterized by continuous application on the part of any but a very small minority, as any one observant of the habitual demeanor of juvenile pupils will testify. There are always some who learn their lessons with surprising quickness; these require to be kept back rather than urged forward, and should be allowed much play with their study. There are many more who are in no danger of ex-

cessive mental development, will never apply themselves to their books at their homes, and need all the study hours of the legal school-day for the accomplishment of their necessary tasks.

There are other aspects of the subject which we desire to take up. Mathematics, grammar, rhetoric, and other abstruse and difficult studies should be assigned to the morning hours, when the brain is fresh and vigorous; geography, history, reading, and writing, which demand less intense application, may more advantageously come up later in the day, when the mental powers are less keen. This Dr. Higgings has suggested in a late number of the *Popular Science Monthly* (Study Physiologically Considered).

Little need be said about the necessity, recognized by all institutions of learning, of bodily exercise, and it were better almost that the boy should grow up a dunce than a puny, feeble, sickly man. Even in young ladies it is now being generally conceded that a robust physique is a desirable thing, and seminaries for females are provided with play-grounds and places for gymnastic exercises.

With regard to diet we cannot too strongly insist on the need of good food as a condition of effective study. There is little danger of overfeeding in children; excess is rather the vice of adults than of the young, and the appetite is generally a safe guide. "How peremptory is the demand of the unfolding organism for materials is seen alike in that school-boy hunger which after life rarely parallels in intensity, and in the comparatively quick return of appetite." Herbert Spencer, in his treatise on Education, previously quoted from, makes some very practical suggestions under this head, which we shall do little more than condense. The degree of energy essentially depends on the nutritiousness of the food. Where energy as well as growth has to be maintained it can only be done by high feeding. Though a child of whom little is expected in the way of bodily or mental activity may thrive tolerably well on farinaceous substances, a child who is daily required not only to form the due amount of new tissue, but to supply the waste consequent on great muscular action, and the further waste consequent on hard exercise of brain, must live on substances containing a larger ratio of nutritive matter. And is it not an obvious corollary that denial of this better food will be at the expense either of growth or of bodily activity, or of mental activity, as constitution and circumstances may determine?

We propose to return to this subject in a future number.

DR. THOMAS TROTTER, PHYSICIAN TO THE FLEET.

IT is always a pleasure to add to one's list of friends a man whose aims are upright and whose talents distinguish him above those with whom he is in daily contact, and who at the same time is genial, warm-hearted, and well educated. That the man no longer walks the earth but lives only in his works does not necessarily diminish the pleasure in making his acquaintance. Dr. John M. Browne, U. S. N., figures in the last publication of the Proceedings of the Naval Medical Society as the author of an essay which he entitles An Hour with Dr. Thomas Trotter, Physician to the Fleet. Dr. Browne invited the attention of his hearers to the sanitary condition of the Royal Navy nearly a century ago, and to the multiform industry of a single individual, Dr. Trotter, in the acquisition of the knowledge of disease and of its cure and prevention, and in whatever pertained to the good of the service; whose indefatigable endeavors to mitigate the pernicious effects of scurvy, and eminent success in repressing the contagious or putrid fever, and whose general work of administration are so clearly, tersely, quaintly, and delightfully set forth in his *Medicina Nautica*.

Dr. Trotter's character is so charmingly set forth in Dr. Browne's essay and so illustrated by extracts from his writings, that we venture to say that its appearance has caused more than one copy of his books to be drawn from its dusty hiding place and that the charm of the *Medicina Nautica* has been found to exist equally in the other volumes.

There is a genuiness, a charming homeliness and simplicity in his mode of expression, that keeps the attention constantly alive. His devotion to duty, patient effort, pursuit of the practical, and true directness of purpose make his conclusions possessed of no other motive than fidelity to honest conviction.

New duties and responsibilities, which demanded independence of thought and self-reliance of character, were met and performed in a manner that made him an acknowledged authority. There are many evidences of his generosity, charity, philanthropy, and patriotism. Seemingly, he was a clever, ready, perceptive and receptive man, gifted with clear, strong, good sense; with an inquiring and studious habit of mind; genial, earnest, steadfast, sincere, and untiring — and his own nature was evidently of a gentle, charitable, and humane quality. Such is the description of the man drawn from his writings as summarized by Dr. Browne.

In addition one might say that he was a man of keen powers of observation, who could record facts as they existed without regard to existing theories and preconceived ideas. He saw with his own eyes and drew his own conclusions. He commenced early in his medical career to think for himself. He was very anxious, he tells us, that the subject of his Inaugural Dissertation when a candidate for the degree of Doctor of Medicine in the University of Edinburgh, in 1788, should be something that had never been noticed by any former graduate. This condition was fulfilled in his thesis *De Ebrietate ejusque Effectibus in Corpus humanun*. For this essay he received the thanks of the Royal Humane Society transmitted by Dr. Hawes, the illustrious founder of the institution, who observed that "the investigation of so important an inquiry, in a regular scientific manner, was never before thought of: it was a subject left, happily left, to be ingeniously executed and amplified by Dr. Trotter."

He possessed to a great degree the power of perceiving abuses of all sorts, and seems to have had that unusual ability of telling the evils that he saw, and desired to reform, in a manner that enlisted the sympathy of those in power, and aroused the least possible opposition in those interested by the sincerity and unselfishness of his motives. Impressment, want of uniform clothing, deficiencies in diet, improper hospital accommodations, are evils to which he returns again and again in different books, and to which he devotes even more attention than to the selfish disregard of the government for the medical officers of its navy. He does not hesitate to express himself clearly and with the authority born of an upright purpose in regard to reforms that he has at heart, as after speaking of his method of preserving water on voyages by charring the inside of the casks, he says, "I am not, however, satisfied with the attention the Victualing Board has given to this method, and it has never yet been practiced from sufficient authority."

He was a man of accurate scholarship and varied reading. The Latin authors are quoted sufficiently often to show that they had not slipped from his memory, and writers in the continental languages on the subjects which lay nearest his heart did not escape his attention, but if we may judge by the frequency and aptness of the quotations, the favorite companion of of his solitude, the prominent occupant of the shelves of his cabin, must have been Shakespeare.

To the striking peculiarities of the seaman he finds it necessary to devote much time, and begins with the earliest stage of the seaman's life: —

"The love of adventure and enterprise that so soon discovers itself in an active boy seems to prompt the first inclination for sea. . . . Among boys of this description the history of a broken sailor is accounted the finest piece of eloquence, and wherever he appears the narration of his voyages, battles, and shipwrecks are listened to with rapture. The voyages of Drake and Anson round the world are famous in this way, and eagerly read by school-boys, but Robinson Crusoe has made more proselytes to these kinds of adventures than all other mariners. His story, from first to last, is so full of incident; in all his difficulties he shows so much courage, address, and ingenuity, that the young reader fancies himself the discoverer of some great kingdom, and his imagination wanders in search of an island."

He describes the characteristics of the sailor due to the isolation of his sea life, his narrow-mindedness, his credulity and superstition, his heedlessness of the future, his peculiarities of speech, and his tendency to work upon the credulity of his hearers.

He then turns to his virtues, which, with a sailor's partiality for his own profession, he says are of the finest cast, and ends his eloquent tribute with the declaration, "Was I ever to be reduced to the utmost poverty I would shun the cold threshold of fashionable charity to beg among seamen, where my afflictions would never be insulted by being asked through what follies or misfortunes I had been reduced to penury."

Some new traits are engrafted on the character by coming on board a man-of-war, and by the custom of impressment, which he condemns as a most fatal and impolitic practice. "It is the cause of more destruction to the health and lives of our seamen than all other causes put together." Many a melancholy story is related to the medical attendant of a sailor, and it begets a sympathy that interests us the more in their recovery. Under this species of mental affliction numbers perish without any apparent disorder.

Certain other of Dr. Trotter's writings are as interesting as his essays on naval medicine. His treatise on scurvy advocates nearly the opinions of the present day, and shows him as an accurate observer, especially in his arguments against the theory of its contagious nature. It also shows the disadvantages of the naval surgeon's position, which he labored so earnestly to improve. "The author of the Observations, at the end of the last war, by no provision being made for the junior part of the Surgeons' List, was the first man of his *corps* who had to embrace the painful alternative of embarking on an African voyage. Much of the information contained in these pages was the result of his practice in that voyage. To find that it is of any service to medical science will, in some degree, repay him for the unpleasant months he spent in the unhallowed trade, and the sufferings of his constitution from an unwholesome climate." The Observations contain many interesting details of the disease, and a moderately full account of the voyage of the slaver. It is evident that the worthy doctor's inferences on the cruise were not confined to the physical effects as shown by the outbreak of scurvy, as a footnote on one page of the volume refers to Dr. Trotter's evidence on the slave trade before the Select Committee of the House of Commons, and we are delighted to find him using, at the close of the book, a now well-worn phrase, when he says that "few think they are trampling on the rights of a Man and a Brother."

The following quotation shall serve alike to show the zeal and energy of the Physician to the Fleet, and also the animated style of his composition: —

"It was of little moment whether the sallad ought to be considered as a part of the victualling or medicine; the public service demanded instant releif. Had it been in my power to command it, it should have been brought from the Land's-End in Cornwall before the fleet had so long groaned under the affliction. We have heard of a Minister ordering a train of ordnance across the country from Woolwich to Portsmouth to save time; in this manner would I have wheeled the product of every distant garden to Portsmouth, lest the tooth of a sailor should drop from his gums by a tardy conveyance of his deliverer. *Deliberat Roma, perit Sagantum.*" . . .

"The reader may smile at the idea of a Physician to the Fleet attending the stalls at a vegitable market, or perambulating the country to calculate the produce; but it never appeared to me below the dignity of the profession; nor did I consider it a mean task to serve the sallad with my own hands from the Charon's quarter-deck."

The last cases in which Dr. Trotter administered

the juice of lemons and oranges for the cure of scurvy he thought worth narrating, and they still retain an interest for us. Some time in November, 1789, eighty Irish convicts came from Newfoundland in company with the ships returning from that station to England. These convicts to the number of 130 or 140 had been shipped at Dublin some time before. "The master of the vessel in which they sailed had orders to land or dispose of them somewhere in the territories of the United States of America. Instead however of fulfilling his contract with government and obeying orders," he received money from his prisoners for their liberty and then turned them on shore at Newfoundland, where many perished in the woods from hunger and fatigue, and the remainder were finally taken in charge by the naval commander on that station and returned to England, when they came under Dr. Trotter's care.

But these extracts are all too few to give any adequate idea of the charm of his writings, or appreciation of his personality as revealed through them. As a naval hygienist he must have been far in advance of his age; the same number of the naval journal that contains the account of this interesting man contains also an account of thirty years' progress in our own navy, from which one may infer that all the improvements Dr. Trotter advocated have not yet been fully accomplished. We are reminded of Dr. John Brown's essay on Dr. Henry Marshall and Military Hygiene. Dr. Marshall and Dr. Trotter seem to have been singularly alike in their devotion to the private soldier and sailor, alike sanitarians before that word had an existence, alike in their devotion to their profession, and through it to our common humanity.

MEDICAL NOTES.

— Dr. Morris Longstreth, of Philadelphia, is delivering a course of lectures at the Lowell Institute, in Boston, on the Germ Theory of Disease. A very agreeable reception of medical men and others, to meet Dr. Longstreth, was held lately at the house of Dr. B. S. Shaw.

— The JOURNAL has previously alluded to the *couveuse* or artificial nest in use at La Maternité in Paris for containing premature and feeble infants. M. Auvard, who has recently published an account of its practical operation (*Archives de Tocologie*, October, 1883, and *Le Progrès Medical*, March 1, 1884), gives the following figures as to its record from November, 1881, to July, 1883: —

	Total.	Lived.	Died.
Premature births	93	62	31
Asthenia	6	4	2
Cyanosis	5	5	–
Œdema	25	21	4
Apparent death	4	3	1
Respiratory difficulty	5	2	3
Innutrition	3	1	2
Syphilis	4	4	–
Obstetrical operation	2	2	–
Fracture	1	1	–
Vice of conformation	3	–	3
Total	151	105	46

The fortunate results are thus seen not to be confined to cases of premature birth. In œdema the mortality was only four in twenty-one, while Professor Depaul gives sixteen deaths in twenty as the ordinary proportion in this malady.

The writer points out the infrequency with which infants weighing from 1600 to 1800 grammes are saved, in spite of most assiduous care, which of course cannot be given in a hospital as it could be in a well-to-do family in private life. Of the prematurely born in the foregoing table seventy-nine weighed less than 2000 grammes. Of these forty-nine survived, giving a mortality of thirty-eight per cent; while in l'Hôpital Cochin in 1882 the mortality in children of this weight without a couveuse was sixty-six per cent.; in the Maternité, during the two years preceding the use of the couveuse, sixty-five per cent.

— At a recent meeting of the Obstetrical Society of Edinburgh one of the speakers referred to the danger which, in his opinion, existed in the lying-in room from menstruation, saying that he believed he could trace certain cases of puerperal fever to want of proper cleanliness on the part of the nurse who happened to be menstruating at the time.

NEW YORK.

— Two brothers who died of typhoid fever within twenty-four hours of each other, at Schenectady, N. Y., were buried together on the 12th of March, and two other brothers are ill with the disease, which was caused by drinking water from a well into which a cess-pool drained. The well was ordered closed by the Board of Health. The city of Schenectady has as yet no system of sewers, and it is now proposed to have one constructed.

— Three cases of typhus fever were recently discovered in a down-town lodging house. On the 5th of March a tramp suffering from the disease was removed from there to the Riverside Hospital, Blackwell's Island, and on the 8th it was found that two new cases had become developed. They were also taken to the hospital.

— A meeting of registered drug clerks was held at the College of Pharmacy, March 11th, for the purpose of aiding in the enforcement of the pharmacy law, and the members of the association bound themselves to report to the chairman of the executive committee the names of all druggists known to them who employed unregistered clerks, or who were unregistered themselves, as well as the names of such unregistered persons.

— A reception, designed as an informal housewarming, was held by the Faculty of the New York Post-Graduate Medical School at their new building in East Twentieth Street on Friday evening, March 21st.

— During the past week the State Senate Committee on Public Health has been making an investigation into the alleged illegal manufacture and sale of imitation and adulterated dairy products, the principal attention being devoted to the subject of oleomargarine, but the results of the investigation have not yet been made public. In the course of it Dr. H. A. Pooler, of Goshen, formerly connected with the New

York Board of Health, and now a member of the Orange County Board of Health, endeavored to show that in New York the number of still-births had increased out of proportion to the natural increase of population with the increased consumption of oleomargarine, — the reported number in the year 1883 being 506 more than in 1876, — and he attributed this to the benne and cotton-seed oil used in its manufacture. He and other physicians testified to the injurious effects of nitric acid, also used in making it; but rebutting testimony was brought forward to the effect that in the diluted manner in which this was employed it was not injurious. It was also stated that boiled pork, which requires one hour and forty-five minutes longer, and boiled beef suet, which requires two hours longer to digest than melted butter, were the two principal ingredients of oleomargarine.

— Dr. E. H. Bartley, chemist to the Brooklyn Board of Health, has made a report to that body in regard to the "rock-and-rye drops," which, although flavored with fusel oil, are constantly sold at the candy shops in large quantities to school children, and in it he says: In some of these candies the oil is not thoroughly mixed or diffused, and occasionally a good-sized cavity is filled with fusel oil. Estimating that a child may buy and eat a half pound of this candy, containing 5.7 grains of the oil, it will be seen that it will take the maximum dose for an adult, and will probably experience distinct symptoms, such as dizziness, headache, or even slight intoxication. A fatal dose of fusel oil is stated by the best authorities to be from 1.4 to 1.6 grammes, or the quantity found in two pounds of this candy.

— Dr. H. T. Hanks has devised a combined day-book and ledger for physicians (published by J. H. Vail & Co.), which, on account of its extreme simplicity, will, no doubt, prove a god-send to the busy practitioner who keeps his own books. On account of this simplicity its plan is certainly preferable to any of the methods now in use among the profession, and it has the additional advantage of rendering it possible to keep at the same time an exact record of all charges and payments, complete in the minutest detail, as well as to continue the account from year to year without reëntering, so that there is no waste of space. The author's claim to have arranged in this book the most exact and labor-saving system of book-keeping ever devised for the use of the physician would seem, therefore, to be a substantial one.

Correspondence.

LETTER FROM LONDON.

London, *March* 7, 1884.

Mr. Editor, — As I intimated in a former letter, Dr. John Williams's paper On the Corroding Ulcer of the Os Uteri, which was read to the Obstetrical Society last Wednesday evening, proved very interesting.

The communication was based on three cases, two of which had been under observation for between nine and ten years, the other for about two years. In the former the conditions had probably not existed long when first seen; but in the latter case the ulcerative process may have been going on for years.

Although this disease is very rare it is undoubtedly occasionally met with and mistaken for epithelioma. It is, however, quite distinct from cancerous disease, — for throughout its course the uterus remains free and movable and the glands are not affected. The disease is characterized by discomfort and a burning sensation, but there is little or no actual pain. Hæmorrhage is unimportant; but there is a more or less constant white or brownish discharge, which is very fetid. Examination shows a small ulcer on the uterine lip, which gradually enlarges, eating away the underlying tissue until the cervix is excavated, as in cancer.

Of Dr. Williams's three cases, one died at an advanced age with hemiplegia; another of uræmia; while the third is still alive, healthy and well-nourished. She has been married twice, and contemplates a third union, — which goes to show that the "corroding ulcer" *per se* is neither fatal to life or happiness. In the case of the patient dying of uræmia from kidney disease, an autopsy was made. As already stated, there were none of the characteristic conditions met with in cancer present. Microscopic examination showed nothing different from what is found in ordinary ulcer. There was a small cell — probably inflammatory — infiltration.

In one case there was some hypertrophy, with formation of nodules around the margin of the ulcer. Dr. Williams considers that this case was one of lupus.

Another case he concluded was that of slowly progressing senile gangrene, for the arteries, especially the iliacs, had undergone calcareous degeneration and broke down under the fingers. This disease was described many years ago by Sir Charles, and his brother John, Clark. Since then little has been written about it.

The President, Dr. Gervis, thought that Dr. Williams had established the existence of such a disease as corroding ulcer of the os uteri, and that it was of great importance to distinguish it clinically from cancer in regard to the prognosis.

Dr. Priestly, looking back over his practice, thought he could remember several cases which at the time were considered cancer, but which were undoubtedly corroding ulcers.

Dr. Matthews Duncan had had a large experience, and had been studying the subject for years, but he was bound to confess that he had never seen a single case of corroding ulcer. He believed that without doubt the conditions which Dr. Williams had described were nothing else than lupus. A number of other prominent members took part in the discussion.

For my own part I do not see that Dr. Williams has established that "corroding ulcer" is entitled to be considered as a distinct disease, but rather as a generic name for all destructive ulcerations of the cervix. Dr. Williams used the word "malignant" in his paper, and afterwards explained that he meant by that term merely that the disease was not curable.

Emmet, in his very scanty remarks on this subject, considers that corroding ulcer is malignant in the usual sense of the word, but as no histological description of the condition is given, one might well imagine that he was dealing with carcinoma uteri pure and simple.

All the German authorities which I have consulted refer to Clark's original paper, and declare that if such a condition — distinct from cancroid or carcinoma —

exists it must be extremely rare; and more than one suggests that the English observers may have mistaken the disease for certain conditions of the above or lupus.

The discussion of the cold-bath treatment of enteric fever, which recently occupied two evenings of the London Medical Society, excited much interest, and, as Dr. Broadbent said, marks an epoch in the treatment of that disease. The sense of the Society was decidedly in favor of the bath, pack, or sponging, and the statistics collected by Dr. Coupland and others seemed to justify this.

A surgical ward has been opened in the children's department at Dorset House branch of the Samaritan Hospital, and placed under the care of Mr. W. A. Meredith.

Last week Mr. Meredith removed a sarcomatous kidney from a girl four years old. The tumor, which extended from above the ensiform cartilage down into the pelvis, on the right side, was first noticed by the patient's mother four weeks ago. Since then it has rapidly enlarged. The contents of the tumor was soft and almost diffluent, so that in removing the mass it was considerably broken up. The whole weighed two and a half pounds. The child died of septicæmia on the third day, and at the autopsy the lungs were found to be studded with secondary sarcomatous deposits.

Mr. Skene Keith has resigned his position as assistant surgeon to the Samaritan Hospital, and will, I understand, return to Edinburgh.

Permit me a non-professional word in closing. It is the general opinion of Americans here that the Longfellow bust recently placed in Westminster Abbey is a worthy tribute to America's greatest poet. The likeness is excellent. Lord Granville was overheard by a friend of mine to remark, when the bust was unveiled, "If my mother had given me such a head as that I might have been a poet too."

Yours truly, W. P. M.

Miscellany.

THE OHIO STATE MEDICAL SOCIETY AND MEDICAL EDUCATION.

THE Trumbull County (Ohio) Medical Society has issued a circular addressed to the "Members of the medical profession interested in the elevation of the standard of preliminary education," proposing a list of subjects in which all applicants for admission as students of medicine under the tuition of members of the State Society should be required to pass before a board of Medical Examiners appointed by the State Society. The schedule of subjects for examination is the same as that laid down in a resolution by the Medical Society of the State of Pennsylvania in 1878, and adopted in 1883.

At the meeting of the Trumbull County Medical Society called to consider this subject, the following resolutions, among others, were adopted: —

"That no member of this Society shall receive any person as a student of medicine unless he present a favorable certificate from the Board of Medical Examiners.

"That the time of study required by members of this Society shall be five (5) years, including lectures.

"That members of this Society shall recommend their students to attend only such medical colleges as either require an examination for admission similar to the one required by this Society or make the full three years' graded course of study obligatory for graduation therefrom, and otherwise endeavor to elevate the standard of medical education.

"That this Society requests the Ohio State Medical Society to adopt the foregoing schedule of requirements and to use its influence to secure legislation making the same obligatory upon persons entering their names as students of medicine in the State of Ohio."

HYDATID CYST OF THE ABDOMINAL WALL.

A CASE is reported in *L'Union Médicale* (17th February, 1884) of a somewhat unusual character, occurring in the service of M. Polaillon. The patient, aged sixteen, printer, had had no history of previous illness except a fall from a third story a year before, which had left no mark, but which had been followed in a month by the first development of the present tumor. The swelling was situated in the right iliac fossa; had always been painless except that for the few days before he came under observation there had been a little discomfort. In July, 1883, he entered the hospital with an ovoid tumor in the right iliac fossa, having its long axis parallel with the inguinal fold, non-reducible, fluctuating, and of the size of a cocoa-nut. The skin was healthy and movable. The growth seemed to occupy the thickness of the abdominal wall. The good health of the patient and the absence of any sign of bone disease made an abscess seem improbable. There was, moreover, a sonorous zone between the tumor and the liver, and there was none of that peculiar quiver on percussion which is supposed to characterize hydatid of the liver. The tumor was aspirated, giving a clear, serous, slightly yellowish, urine-like fluid, which showed, under the microscope, red and some white globules. No hooklets, but a little shred of membrane resembling that of a hydatid cyst. A few days after the puncture the patient left the hospital, but the fluid began to accumulate again, and he returned August 15th with the tumor as large as ever. A second puncture gave a fluid which showed a few hooklets. The diagnosis was then made of hydatid cyst of the abdominal wall. A free incision was made, and the cavity washed with carbolic solution, one to twenty. Two days later there was some headache, but no local pain, and but little fever. Suppuration ensued, and the pus accumulated in the sac to the size of a fœtal head. August 28th another incision of three centimetres was made, and pus flowed. Drainage and Lister dressing were used. The carbolic irrigation was repeated every two days. Occasionally the washing brought away shreds of membrane. The suppuration was moderate, and the health excellent.

During September and early October the cavity did not close, but the patient felt well, and was up daily. October 18th he was suddenly seized with pain in the iliac fossa, and the next day there was found, engaged in the orifice, a large, thick, hydatid membrane. Attempts to withdraw it by forceps tore it, but compression on the abdominal walls brought it out entire. It was followed by a gush of thick, greenish, and fetid pus. The membrane expelled was white, two to three millimetres thick; it formed an oval sac as big as a fœtal head. It was made up of layers of transparent, structureless, lamelliform substance like the fragments

which had before been washed out. On the interior wall of the sac there were no traces of other hydatid cysts. A rapid diminution of the purulent secretion followed, and November 19th the cavity was closed, the fistulous orifice was healed, and there was no retraction of the abdominal wall.

REPORTED MORTALITY FOR THE WEEK ENDING MARCH 15, 1884.

Deaths reported 2531 (no reports from Chicago, Cincinnati, and Milwaukee): under five years of age, 862: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 434, consumption 404, lung diseases 387, diphtheria and croup 138, scarlet fever 59, diarrhœal diseases 45, measles 42, typhoid fever 41, malarial fevers 23, cerebro-spinal meningitis 21, small-pox 20, whooping-cough 19, erysipelas 13, puerperal fever 13. From *measles*, Baltimore 15, New York and New Orleans eight each, District of Columbia four, Brooklyn three, Nashville two, Philadelphia and Lawrence one each. From *typhoid fever*, Philadelphia 21, New York five, Boston three, District of Columbia, Pittsburg, Worcester, and Westborough two each, Brooklyn, Baltimore, Lawrence, and Merrimac one each. From *malarial fevers*, Brooklyn seven, New York six, Baltimore four, New Orleans three, St. Louis two, Philadelphia one. From *cerebro-spinal meningitis*, New York and Lowell three each, Lawrence two, Philadelphia, Boston, Baltimore, St. Louis, New Orleans, Worcester, Cambridge, Springfield, New Bedford, Taunton, Melrose, Dedham, and North Andover one each From *small-pox*, New Orleans 19, Pittsburg one. From *whooping-cough*, New York five, Boston three, Philadelphia, Brooklyn, Baltimore, New Orleans, and District of Columbia two each, Gloucester one. From *erysipelas* Brooklyn five, New York four, Philadelphia three, Boston one. From *puerperal fever*, New York and Philadelphia three each, Brooklyn two, Boston, Baltimore, St. Louis, Nashville, and Newburyport one each.

Two cases of small-pox were reported in St. Louis; scarlet fever 53, diphtheria 30, typhoid fever 17, and measles one in Boston; measles 16, scarlet fever six, and diphtheria five in Providence.

In 101 cities and towns of Massachusetts, with an estimated population of 1,428,666 (estimated population of the State 1,955,104), the total death-rate for the week was 17.07 against 20.31 and 18.00 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending March 1st, the death-rate was 20.3. Deaths reported 3417: acute diseases of the respiratory organs (London) 334, whooping-cough 121, measles 87, scarlet fever 75, fever 40, diarrhœa 37, diphtheria 29, small-pox (London eight, Sunderland six, Birmingham two, Liverpool and Sheffield one each) 18. The death-rates ranged from 12.1 in Norwich to 29.5 in Manchester; Birkenhead 15.5; Leicester 16.9; London 19.3; Leeds 20.1; Birmingham 21.4; Blackburn 21.7; Sheffield 21.9; Bristol 22.3; Nottingham 23.1; Liverpool 23.3; Sunderland 23.7. In Edinburgh 20.1; Glasgow 27.7; Dublin 25.7.

For the week ending March 1st, in the Swiss towns, there were 33 deaths from lung diseases, consumption 28, diarrhœal diseases 27, typhoid fever nine, diphtheria and croup six, whooping-cough five, measles, scarlet fever, and puerperal fever each one. The death-rates were, at Geneva 24.5; Zurich 17.7; Basle 12.4; Berne 27.8.

The meteorological record for the week ending March 15th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OBITUARY. DR. L. P. YANDELL.

DR. L. P. YANDELL, of Louisville, Ky., Editor of the *Louisville Medical News*, and an incumbent successively of chairs of Materia Medica and the Theory and Practice of Medicine in the University of Louisville, has recently died at the age of forty-seven. He was of a family of note in the medical profession in the South, and leaves a brother, Dr. David W. Yandell.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM MARCH 15, 1884, TO MARCH 21, 1884.

BACHE, DALLAS, major and surgeon. Leave of absence still further extended seven days. Paragraph 1, S. O. 50, headquarters Department of the East, March 14, 1884.

MATTHEWS, WASHINGTON, captain and assistant surgeon. To be relieved from duty in the Department of the Missouri, and to report in person to the Surgeon-General of the Army for duty in his office. Paragraph 12, S. O. 62, A. G. O., March 15, 1884.

BLACK, CHARLES S., first lieutenant and assistant surgeon. Assigned to duty at Fort Concho, Texas. Paragraph 6, S. O. 30, headquarters Department of Texas, March 10, 1884.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING MARCH 22, 1884.

STREETS, T. H., passed assistant surgeon, from Museum of Hygiene, Washington, for duty in the Coast Survey Service.

HALL, C. H. H., passed assistant surgeon, from the Naval Academy to the Museum of Hygiene.

STEWART, HENRY, surgeon, ordered before the Retiring Board.

SUFFOLK DISTRICT MEDICAL SOCIETY. SURGICAL SECTION. — There will be a meeting of the Section at 19 Boylston Place on Wednesday evening, April 2d, at 7.45 o'clock. Communication: On Operative Interference on Curved Bones in Children, Dr. E. H. Bradford.

S. J. MIXTER, *Secretary.*

BOOKS AND PAMPHLETS RECEIVED. — A Companion to the United States Pharmacopœia, being a Commentary on the Latest Edition of the Pharmacopœia, and containing the Descriptions, Properties, Uses, and Doses of all Official and Numerous Unofficial Drugs and Preparations in Current Use in the United States, etc. Designed as a Ready Reference Book for Pharmacists, Physicians, and Students. With over 650 Original Illustrations by Oscar Oldberg, Phar. D., and Otto A. Wall, M. D., Ph. G. New York: William Wood & Co. 1884.

Legal Medicine. Vol. II. Legitimacy and Paternity, Pregnancy, Abortion, Rape, Indecent Exposure, Sodomy, Bestiality, Live Birth, Infanticide, Asphyxia, Drowning, Hanging, Strangulation, Suffocation. By Charles Meymott Tidy, M. B., F. C. S., etc. Philadelphia: Henry C. Lea's Son & Co. 1884.

Spinal Irritation. Probable Cerebral Origin of the Symptoms sometimes classed under this Head. By G. L. Walton, M. D. (Reprint.) 1884.

Neglect of Ear Symptoms in the Diagnosis of Diseases of the Nervous System. By G. L. Walton, M. D. Boston. (Reprint.)

Thirtieth Annual Report of the Trustees of the State Lunatic Hospital at Taunton for the Year ending September 30, 1883. Boston. 1884.

Report of the Memorial Meeting of the Medical Society of the District of Columbia in Honor of Dr. J. Marion Sims. Held November 21, 1883. (Reprint.)

Excerpts from Prof. Hugo Schulz's Treatise on Eucalyptus Oil. Translated and Supplemented by Baron Sir Ferd. von Mueller, K. C. M. G., etc., Government Botanist in Victoria. (Reprint from Australasian Medical Gazette for 1883.) Sidney. 1883.

Ueber das Verhalten des Catgut im Organismus und über Heteroplastik. Van Dr. L. von Lesser, Privatdocenten der Chirurgie in Leipzig.

Lectures.

INSULAR SCLEROSIS OF THE POSTERIOR COLUMNS OF THE SPINAL CORD.

A CLINICAL LECTURE DELIVERED AT THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.[1]

BY WILLIAM PEPPER, M. D., LL. D.,

Professor of Clinical Medicine in the University of Pennsylvania.

GENTLEMEN, — This patient has been sent to me by a friend in the city, who states that he thinks that this man has sclerosis of the posterior columns of the spinal cord or progressive locomotor ataxia. He gives the following history: He is forty years old, a farmer, married; has been married for seven years. Has one child, who is three years old and healthy. The symptoms of the present disease manifested themselves in February, 1881. While loading hay he slipped, but apparently did not hurt himself much. The following day the legs began to get stiff and numb. He, however, continued to work until August, 1882. The limbs were not as strong as before, but he was still able to do his work, and walk twenty miles in hauling hay to the city. In May of 1882 one eye began to fail, and seven months ago the second eye began to be affected. He thinks that if he could see he would be able to work as well as before. About the time that the numbness first appeared he had occasional pains in the limbs, but during the past year they have, at times, been unbearable. They shoot through the thighs like lightning, darting from one joint to another, and from one leg to the other. These pains are worse at night. About a year ago he had severe shooting pains across the forehead. He has had no pains in the arms. The parts where the pain appeared never became red and swollen. There have then been fulgurant pains through the limbs, presenting the characteristics of those met with in ataxia. With this perverted sensation there have been some numbness and tingling, some impairment of feeling, and some loss of power, with amaurosis coming on within the last year, the amaurosis being preceded by fulgurant pains in the neighborhood of the eyes.

Let us now study further in regard to the development of the symptoms. There has been no jerking of the legs. He has not lost much flesh, but the limbs are somewhat wasted. Appetite and digestion are good. He states that once in a while he has bilious spells, but does not vomit at such time unless he has sick headache. He is very subject to sick headache, having, on an average, an attack about once a month. The bowels are regular, and there is no trouble with the bladder. There is a total absence of bladder and rectal complication. The time at which these organs become involved varies, but, as a rule, they are affected sooner or later.

There has been present in this case that which is frequently met with in ataxia, namely, gastric crises, attacks apparently not dependent upon indiscretion in diet, taking cold, or other obvious cause, in which there is neuralgic pain associated with loss of appetite, nausea, and very often vomiting. Not rarely ataxic cases will be found to present attacks of this kind. In some cases they are extremely well pronounced, while in other cases the disease runs its entire course without the appearance of such attacks. I do not know that I am right in saying so, but I think that my experience will bear me out when I state that these crises are more marked where amaurosis is present and distinct. Where sclerosis of the higher centres governing the eyes makes its appearance disturbance of the pneumogastric tract is more common than when the sclerosis is limited to the posterior columns of the cord.

So much, then, for the history, which points to progressive locomotor ataxia. Let us now see if the present condition bears out this suggestion, first directing our attention to the eyes, then to the power of locomotion, and finally to the condition of the muscles of the affected part.

The right eye was the one first affected, but both are now in about the same condition. He can distinguish light from darkness, and that is about the extent of his vision. This man unquestionably has degeneration of the optic nerve and retina, but the eyes will be subjected to a careful ophthalmoscopic examination. These degenerative changes are found in locomotor ataxia when the sclerosis involves the higher centres.

He states that he has no difficulty in walking except that which is due to his inability to see where he is going. Before the eyes were so much involved he was able to walk twenty miles a day with a load of hay in all kinds of weather. The legs, he thinks, do not feel so stiff as they used to. As he walks across the floor he certainly walks very well, but, as you see, there is a certain amount of incoördination of the muscles; but when the length of time which the disease has lasted and the condition of the eyes are considered the amount of incoördination is extremely small. He is not at all giddy.

Examining the patella reflex I find that there is no response whatever in either limb. The condition of the reflex patella and ankle furnish interesting and important signs which you should always study in cases of suspected organic change of the spinal cord. As you are aware, irritation of certain areas of the skin produce certain reflex movements of the muscles of other parts of the body, so that by a study of these reflex movements the location of the disease of the cord can often be determined. Thus irritation of the skin of the inside of the thigh produces a cremaster reflex, while irritation of a patch of skin a little higher produces a reflex movement in the muscles of the abdomen. These symptoms are always worthy of study. I have been a little disappointed in the use of these signs, because I have found cases of functional disease of the cerebro-spinal axis where the patella reflex was totally lost, and yet where the course of the case proved conclusively that the affection had been one merely of anæmic exhaustion without any organic disease whatever. I find that others have observed the same thing. The law laid down as to the absolute pathognomonic value of the absence of patella reflex as a sign of advanced posterior sclerosis must be regarded as subject to exceptions. At the same time it is a symptom that possesses a certain value, and when we find, in connection with fulgurant pains and incoördination of the legs, a total loss of patella reflex we know that in all probability there are changes in the posterior columns of the cord.

In this patient the legs feel numb, but sensation is not entirely lost. This is commonly the case. A critical study of the condition of sensation, for which we

[1] Reported by William H. Morrison, M. D.

have not time to-day, might reveal that in some areas there was actual loss of sensation, while in others the anæsthesia was not absolute.

This is not an ordinary case of sclerosis. It is an example of what is called insular sclerosis. This is a rare disease. The posterior columns are affected, but not in the way that they are in ordinary locomotor ataxia. As you probably know, the earliest symptoms of this latter disease are perverted sensation, fulgurant pains, increasing incoördination of the muscles of the leg, and slight wasting, but no actual paralysis. These are the symptoms of the early stage. The disease advances up the posterior columns, following the physiological course of the fibres. As the disease involves a higher portion of the cord the movements of the arm become affected. When the disease has reached the lower cervical region the eyes become involved, and amaurosis is apt to be developed. Later the sclerosis may affect the crura of the brain, and may extend into the expansion of these columns.

In the present instance the disease has pursued a less regular course. There have been unmistakable symptoms of sclerosis, beginning in the lower portion of the cord. There has been perverted sensation, incoördination of the muscles, fulgurant pains, and loss of patella reflex; but these symptoms have not been present to such a degree as to indicate that the entire posterior column had passed a state of degeneration. If this spinal cord could be examined I have no doubt that small islands of gray degeneration would be found scattered through the posterior columns, and, corresponding with the development of the marked ocular symptoms and the severe cerebral attacks, that insular sclerosis had developed high up, possibly involving the crura, pons, or higher centres. These cases of insular sclerosis are less common and less regular in the development of the symptoms than are cases of ordinary sclerosis of the posterior columns, but they are usually recognizable with a little care.

We shall next consider the ætiology, prognosis, and treatment of this case. Of late years there has been an attempt made to establish an absolute connection between sclerosis of the posterior columns and syphilis. Erb and Rosenthal probably represent the advanced advocates of this view. The French, American, and English schools take a more moderate and fairer view of the matter. I have met with a number of cases where the most careful investigation of the individual life and of the family history has failed to reveal any evidence of syphilitic taint. In the present instance the patient positively denies ever having had any venereal disease of any kind. His father died at the age of ninety. His mother is still living at the age of ninety. His parents had ten children, of whom seven are living, and all are healthy except himself. One brother died suddenly of what was supposed to be heart disease, but he does not know what the others died of. The assumption that every case of posterior sclerosis depends on a syphilitic taint is unfounded. The question should, however, always be investigated most critically, because it has an important bearing upon prognosis and treatment. Other causes of this affection are venereal excesses, overexertion, exposure, and the like. In some cases it is impossible to discover any cause. This patient has led a life of hard work and exposure. This may have had something to do with the development of the disease. While it is true that there are a large number of men engaged in farming, and locomotor ataxia is rare among them, yet there are tendencies in certain individuals to certain forms of disease developed by this exposure. He states that he has not indulged in sexual excesses, and that he has not lost sexual desire or power. This retention of sexual powers indicates, as does the retention of control over the bladder and rectum, that the deeper portions of the cord have not become affected, and makes the prognosis more favorable. Unfortunately the disease has involved the centres governing the eyes, and I fear that we shall find that there is no chance of restoring the lost vision. If this is the case the fact that we can arrest the progress of the disease and improve the condition of the limbs affords but little satisfaction.

The prognosis as regards duration of life is, I think, favorable. As far as regards arresting and improving the condition of the limbs it is favorable, but as far as vision is concerned it is unfavorable; but in order to decide this point a careful examination of the eye-ground is necessary.

These are cases for which a great deal can be done in the way of treatment. It is, of course, of the first importance to decide whether the disease is functional or organic, whether the symptoms are due to alteration of the circulation or to actual tissue degeneration. Cases are occasionally seen which present marked symptoms of locomotor ataxia and yet recover absolutely. For instance, not long ago I saw a case like this. A man working hard, with heavy financial responsibilities resting on him, gets into the habit of eating rapidly and irregularly, and takes to using tobacco to great excess, partly for the purpose of taking the place of food which he has not time to eat, and partly to divert the mind. He soon finds that his sleep is disturbed, and that he wakes early in the morning; sick headaches appear, with vomiting spells. Then he finds that he cannot walk at night as well as usual, that his legs get tangled up under him. His gait becomes worse, and people notice it on the street, and think that he is intoxicated. There is a little peculiarity in his appearance, but vision is not particularly affected. The patella reflex is entirely lost, and the man has a high degree of locomotor ataxia. He cannot walk with his eyes shut, and walks with his eyes upon his legs. The cutting off of the tobacco, stopping work, with complete rest, and a prolonged course of careful diet, restores him to absolute health. The ataxia disappears, he gains flesh and strength, returns to his work, and there are no further symptoms of the disease. I have seen such cases repeatedly. When in a case of this kind no cause such as syphilis, excessive venery, the immoderate use of tobacco, or overwork can be found there is more reason to suspect organic change than when some such cause exists.

When a definite cause is found the first thing to be done is, of course, to remove the cause.

If there is no such special cause as has been mentioned it will be found that in the early stages of the disease absolute rest exercises an extraordinary influence over the course of posterior sclerosis. Where a patient presents fulgurant pains, impaired patella reflex, ataxia, and gastric crises you will do well to order such a patient to bed and keep him there for a long time, unless you find that he does sufficiently well with a small amount of carefully-regulated exercise. I have seen cases where there was a distinct development of

the symptoms where I could find no cause which could be regarded as having produced the disease, and where I had no doubt that there was incipient change in the posterior columns, get entirely well by absolute confinement to bed, with carefully-regulated diet, and attention to the state of the muscles. It is the rest which does the good. By this protracted rest symptoms will be relieved which can be affected by no remedies.

I saw the other day an interesting case. A man consulted me for a condition of this kind. I gave him an unfavorable diagnosis and prognosis. He then went to New York, and consulted a prominent physician of that city, who gave him the same opinion that I had done. While walking along the street he slipped, and fell and broke his thigh. This confined him to bed for nine months. When he got well of the fracture he was well of the ataxia. He got out of bed practically a well man. The ataxia and pains had disappeared, and for a considerable time there has been no return of the symptoms. I would warn you against hastily giving an unfavorable prognosis. The removal of the cause and the securing of absolute or at least considerable protracted rest should rank as the first elements of the treatment.

A course of tonic treatment is, I think, always essential. Such patients are nearly always anæmic and below par. They usually do well under large doses of iron when given in some digestible form. The iodide of iron is a valuable preparation in this disease. It is useful in those cases where there is a catarrhal condition and a tendency to pulmonary troubles. The vegetable salts of iron, or dialyzed iron, may also be given. Iron should be used in large doses and long continued. In cases where there is a syphilitic history I need not say that antisyphilitic remedies should be administered. The best form is iodide of potassium in ascending doses until a large amount is taken. You will, however, be disappointed in many of these cases, even though they are originally of a syphilitic character, for the sclerosis, when once established, often resists specific treatment, and although you may arrest the progress of the disease and relieve some of the more troublesome symptoms, especially the pain, the degenerated fibres remain degenerated, and the damage that the disease has done will not be removed. It is not like those cases in which a gumma presses upon the cord. If the gumma is removed the pressure will be relieved and the function of the cord restored. In such a case a perfect cure may be obtained.

In cases where there is no syphilitic history, and yet where, despite the removal of all ascertainable causes, the use of rest, tonics, iron, and cod-liver oil, the disease continues to progress and the irritative symptoms remain, you will find that prolonged courses of nitrate of silver will occasionally exert a beneficial influence. I shall not consider the manner in which this does good. Only under the circumstances which I have mentioned would I recommend the use of this remedy. Nitrate or oxide of silver given in large doses for a considerable period exerts a beneficial influence upon the progress of the disease.

A large number of drugs have been recommended for the treatment of this affection, but I should dread the effect of many of them upon the general health. A vast deal of harm is done by overdrugging. The same is true of the use of electricity. This remedy is usually indicated. If the patient is put to bed it is indicated to supply the necessary exercise. But if the patient is allowed to move about it is not usually demanded. The slowly-interrupted galvanic current is the one to be employed. If the pains are severe this will often relieve them.

This man's condition is one in which it is difficult to give advice. So far as the lower part of the body is concerned we should have no difficulty, but in the presence of this blindness, which I fear is due to organic change in the optic nerve and retina, we shall have to treat him without reference to the head symptoms, and endeavor to restore the power to the legs and arrest the change in the columns of the cord, with the idea that he will learn some new trade which a blind man can practice. The prognosis and treatment must be governed by the condition of the legs.

I should advise this man to go to bed, have the muscles kneaded every day, and take but little exercise. The diet should be carefully regulated. With this I should give remedies to restore the exhausted nervous force, and large doses of iron continued for a long time. I should use no iodide of potassium or other alterative.

Original Articles.

ON MILK SUPPLY IN LARGE CITIES.[1]

BY J. CHESTON MORRIS, M. D.,

Formerly Attending Physician to the Protestant Episcopal Hospital, Philadelphia.

PROBABLY few persons whose attention has not been especially called to this subject have any idea of its importance in an economic as well as sanitary point of view: and it may therefore be well to preface what I have to present to you to-night with a statement, unfortunately only approximate, as full and reliable figures are hard to obtain, of the amount of milk — or what purports to be such — required daily in our large cities.

Dr. H. A. Pooler, of Goshen, N. Y., estimates the amount sold daily in the cities of New York, Brooklyn, and Jersey City, at 500,000 quarts or 182,500,000 quarts annually. I have elsewhere shown from the statistics furnished by the Railroad Companies and the Board of Revision of Taxes, that the amount in Philadelphia alone is 57,548,470 quarts. The supply of Boston I have sought for but have not received a reply from the Secretary of the State Board of Health. But if we compare these figures with the population of the four cities named we find in round numbers as follows: —

182,500,000	quarts consumed among	2,500,000 persons.
57,500,000	" " "	900,000 "
240,000,000	" " "	3,400,000 "

or about 70.6 quarts annually, or not quite ⅔ of a pint daily for each man, woman, and child. This is rather more than the average of England, less than half that of Wales, not one third that of Scotland or Ireland, and far below that of Norway, Sweden, Switzerland, and the Tyrol, as we learn from Edward Smith "On Foods," and Brassey "On Food and Labor." We may therefore fairly conclude that this is not an overestimate of the actual supply in these cities. If we

[1] Read before the Section for Clinical Medicine, Pathology, and Hygiene, of the Suffolk District Medical Society, February 27, 1884.

now multiply these 240 millions by six cents, the *lowest* price paid by the *consumer* for the article, we obtain the amount annually paid by the inhabitants of these four cities, namely, $14,400,000 or nearly $40,000 daily. Surely then we may well pause for a moment to consider what it is that we buy at such a price, and what its real value is to us.

From Simon's Animal Chemistry, vol. ii., p. 62, we may deduce the composition of cows' milk as follows:

Water		860 parts.
Solids, Butter	36 parts	
Casein	68 parts	
Lactin, coloring matter, etc.	30 parts	
Salts	6 parts	
in all —		140 parts.
		1000 parts.

And Dr. P. Vieth in the *Analyst*, for March, 1883, gives the results of 12,430 analyses made for the Aylesbury Dairy Co. in London, during 1882, which practically accord with the above.

A quart of milk, of the average sp. gr. of 1.031 as given by Dr. Vieth, would then weigh at 60° F., about 15,092 grains, of which 12,979 grains would be water, and 2,113 solids. Of the latter there would be

Butter	543.3 grains, or nearly	1¼ oz. avoirdupois.
Casein	1,026.3 grains, or more than	2¼ oz. avoirdupois.
Lactin, etc.	452.8 grains, or more than	1 oz. avoirdupois.
Salts	90.6 grains, or nearly	one fifth oz. avoirdupois.

If we now take these quantities and value them at market rates, say roughly —

1¼ oz. butter @ 30 cents per lb.	.02
2¼ oz. cheese @ 6 cents per lb.	.01
1 oz. milk sugar @ 8 cents per lb.	.005
one fifth oz. phosphates, etc.	.005
	$0.04

we obtain a value of milk which corresponds curiously with its *wholesale price* paid to the producer in the vicinity of Philadelphia and New York and its actual minimum cost of production. The latter may readily be ascertained approximatively by estimating the average annual yield of a good dairy cow at 2000 quarts and the food required at five tons of hay or its equivalent, besides some bran, cornmeal, roots, etc., so that the farmer is only selling his hay at $15 per ton when he receives four cents per quart for his milk, besides taking all the additional labor, investment of capital, and risk of loss.

I have spoken thus of the pecuniary value, let us now consider its food value. By comparing the statements of Valentin, Lehmann, Bidder and Schmidt, Chossat, Béclard and Carpenter, as to the amount of food required daily, with the rations of the British and French armies and those of the United States (as will be seen on referring to my article in the *Philadelphia Medical Times*, June 21, 1879), and with the amount of solids as given above it will be seen that *two quarts* of fresh milk and twelve ounces of bread would be sufficient to maintain a laboring man in full health and strength, the amount of nutritive material being greater than the ration of the French cavalryman. On three quarts milk and twelve ounces bread a man would soon fatten. By comparing the cost of sufficient milk and bread to nourish efficiently a man with that of any other food we shall be struck with its cheapness. But it is not in this that its greatest value lies. It is in the exact adaptation of the various constituents, the fatty, the starchy, the saline, and the nitrogenous, to the wants of the human economy, adaptation both in proportion and kind: so that no other article comes so near to being the universal food of man. Not only does he as all other mammalia depend upon it almost exclusively during the first two years of his existence, but during childhood and adult life milk or its products are essential to our well-being, while for invalids it furnishes the most available and reliable form of nourishment, in many cases the only form. Nor does any mode of preparation enhance its nutritive value. In by far the greater number of instances it is more wholesome and nutritious, more easily digested and more readily absorbed just as it comes from its source than in any other guise. It satisfies the appetite, quenches the thirst, relieves weariness, sustains for the work more surely and quickly than anything else.

Of course its mode of administration and the quantity taken must vary with the age of the individual and the object sought to be attained. We frequently hear from patients the complaint that they do not like milk, and never did, that it never agrees with them, constipates them, etc., etc. Now, in most instances, this is merely prejudice, based sometimes on injudicious mode of taking, or on an inferior article, or on the total absorption of the amount taken which thus leaves no mass of undigested residue to act (as is the case with food containing woody fibre) on the coat of the bowel as a mechanical irritant. If milk is given in divided doses at intervals of three or four hours, to be sipped slowly, while a little bread is eaten with it, it rarely fails to agree with a healthy stomach or even to restore a debilitated one; if there is any sense of oppression it is a good plan to give one or two teaspoonfuls of liquid rennet with, or immediately after, it. While any tendency to constipation may be met by the addition of a little *cream* to the whole milk or the use of a rhubarb pill at night. The benefits of an exclusively milk diet in cases of enfeebled digestion, chronic liver and kidney disease, consumption and impaired nutrition generally, will hardly be believed by those who have not made a thorough trial of it.

Such, then, as briefly as I can give it, is the value of milk from a physiological and medical point of view. No dietary is complete without it or its products, and we all feel keenly its loss when compelled to do without it. But how shall we get it pure and good, — so perishable, so prone to change, so apt to absorb impurities, and to be the carrier of the zymotic elements of disease instead of the genial nourishment which vivifies?

In the country, in small towns and villages, we may fairly attribute the health we often see among those subjected otherwise to many privations to the ease with which this great necessary of life is procured. But as cities grow in size, as more second and third parties have to come between the producer and consumer, the difficulty of procuring reliable, nutritious milk increases. Human cupidity comes in, and the bountiful nourishment is robbed of its richness by degrees; water is added, cream is abstracted, and what is sold to the mother for her hungering babe is but the ghost of its former self. Some years ago, in the Campo Santo, at Munich, I walked through the halls where are laid the corpses of those awaiting interment. That day there were over thirty, and all but two or three were those of children. I asked my guide if any epidemic was raging. He looked surprised, and said "No." When asked how there came to be such an excessive proportion of young children, he shrugged his

shoulders and said, "Many are the children of poor seamstresses and store girls. They have little to eat themselves, and nothing to give their children; the latter are starved and die, often much to their parents' relief." As I looked at the poor, pale, pinched cheeks and wasted bodies, and thought of the effects of cholera infantum, diarrhœa, tubercular enteritis, etc., which play such sad havoc among our children in large cities, the thought occurred to me, how much of all this is the result of the miserable trash with which we delude ourselves and the poor little innocents committed to our care, calling it milk forsooth! Bad air has its victims by thousands, bad food by its tens of thousands. In New York City alone, as I am informed by Dr. H. A. Pooler, the number of deaths among children under five years of age was reduced 3673 in last year below that of 1882 in consequence, as he believes, of the improvement effected there already in the milk supply, the adulteration having been lessened to the extent of 100,000 quarts daily.

Various methods have been devised in the effort to remedy this supply of adulterated milk. Systems of inspection under governmental authority have been largely resorted to, and with excellent effect; they should be increased and made more stringent. But they are cumbersome and expensive, and too often fail to protect the very classes that need it most. The Aylesbury Dairy Company in London has a most efficient and extensive system of inspection and delivery, but this must increase the cost to the consumer. In Paris a Mr. D'Arcy has successfully introduced the method of supply in glass bottles; and in New York Mr. F. Ratchford Starr has done the same; while in Boston Mr. Burnett and others I believe are largely engaged in distributing milk by the same method. I have also been doing so in Philadelphia since 1878, and my example there was followed by a number of others, so that I feel justified by the results of experience in urging the members of our profession and others who are interested in the welfare and health of the community to endeavor to extend the use of milk shipped in glass jars.

The method which I have adopted, for which the Agricultural Society of Pennsylvania awarded me an honorary diploma in 1879, is as follows: —

The cows are well fed, and kept clean: before being milked the udders are always thoroughly freed from dirt. The milk when drawn is strained into a large can in which is suspended a smaller one filled with ice and salt, so as to cool it as rapidly as possible. It is then thoroughly stirred, so as to equalize the distribution of cream; and from a faucet at the bottom of the large can the milk is drawn into quart jars, each of which is then closed and sealed with a label bearing the name and address of the producer and the date of shipment; twenty jars are then packed in a box and sent to the city. The empty jars of the previous day are returned, cleansed, and prepared for shipment again.

The advantages of this method over the usual one among us in large cans are: —

(1.) The milk must be clean; any dirt would show at the bottom of the jar.

(2.) It is free from contamination by foul air, etc., in transit, as the jars are hermetically sealed.

(3.) Each customer gets an exact quart, as the jars must be *filled* to prevent "churning."

(4.) Each customer gets his own share of cream, neither more nor less, as it is put up before the cream has a chance to separate.

(5.) It is for the interest of each producer to send the best article he can, as his reputation — and therefore the price he gets — depends upon the quality of the article which bears his name; and he can guarantee to the consumer, as long as his label is undisturbed, the quality of the article furnished.

And this brings us to the consideration of a most important point. As I have shown, good milk *costs* four cents a quart to produce; but the competition of trade often drives the wholesale price down to three and a half or three cents. In the eyes of the dealer and too often of the too close-buying customer milk is only milk — all milk is alike — and the honest man who sends whole (pure) milk gets no more for it than his neighbor who removes half the cream, or adds a little water "to pay the freight." So long as this is the case in the estimation of the community, so long may they expect to be imposed upon. Just as soon as they recognize the justice and propriety of paying their milk producers in proportion to the quality and value of the article sold there will be no difficulty in having on our tables in large cities milk just as pure, just as good, just as sweet, nutritious, and wholesome, as if taken immediately from the spring house in the country. There is a difference too — and a great difference — in the milk produced by different breeds of cattle. Those commonly known among us may be divided into three groups: the Jersey, or Channel Island; the Devons, or long-horns; and the Durhams, or short-horn. The latter yield abundantly a rather pale blue milk moderately rich in casein, but not in cream or sugar. The Jerseys yield a smaller quantity of milk, rich in yellow cream, but poor in casein and sugar. The Devons, or long-horned red cattle, yield a white milk, nearly equal to the Jerseys in cream, and very rich in casein and sugar, and hence having the highest nutritive value. Next to them comes that from grade Jerseys: next, that from good common cows. That from pure Jerseys is deficient in casein, that from pure Durhams is watery.

I have thus, I think, called your attention to a matter of vital importance, and tried to show the way out of the great difficulties which surround the distribution of milk — pure milk — in large cities. The measure of success which has attended this method and its more and more extensive adoption lead me to hope that in the not distant future its cleanliness and superiority in every respect will put an end to the present milk-can system with all its dirt and liability to fraud and deception.

THE MILK SUPPLY OF BOSTON, AND THE BENEFIT TO BE DERIVED FROM THE SPAYING OF COWS.[1]

BY MR. LLOYD F. ABBOTT.

The milk supply of Boston may be divided into three classes: first, that brought in on the cars, and commonly called railroad milk; second, that brought in wagons from the surrounding country, and called out-of-town milk; third, that from cows kept within the city limits. Each one of these may be divided

[1] Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Suffolk District Medical Society, February 27, 1884.

into three classes: first, from the new milch cow; second, from the farrow cow, or one that has been milked for a year or more; third, from a springer, or one with calf. The nature of the new milk is very loosening; it is well known among farmers that the first milkings given to a calf three or four weeks old will scour it to death. This milk changes as it increases in age, until at the end of a year the milk of a farrow cow becomes very astringent. This milk, if given to a calf a week old, would have exactly the opposite effect of the other. The milk of the springer gradually changes until near calving; it becomes more watery, and has a limey taste.

Let us first consider the railroad milk. The distance from the city and the number of hands through which this passes (all of which have to be paid) make the farmers' returns small. The difference between a farrow cow milked out and a new milch cow is usually from twenty to twenty-five dollars; the farmer can better afford to let his cows go dry from two to three months than to pay the difference. Railroad milk is therefore mostly produced from new milch cows and springers. Let us visit Mr. B.'s dairy. He makes milk the year round and has cows coming in constantly. Some cows may be milked up to the time of calving, but in most cases they will go dry from one to three months, — usually about two, — and will give but little milk for some time before. The low price that Mr. B. receives for his milk and the loss he sustains while his cow is giving none, make it necessary for him to use all that he can of it. This, together with the fact that he does not see or know the parties who use it, makes it natural that he should send to market milk that he would not use himself. Mr. B. commences to milk at one end of the barn; the first cow may be a new milch cow, possibly the first milkings, and will fill, or nearly fill, a can. The next may be a farrow cow that has been milked for a year or more, or may be a springer about to calve; in either case will give but little, and it will take the milk of two or three of them to fill a can. Therefore the milk from the same dairy may be of the greatest possible extremes. Mr. B., having finished his milking, the milk being at a temperature of 100° F., sets it in cold water, which will reduce the temperature to about 55° F. or 50° F. The milk is thus disposed of for the night. The morning's milking is managed in the same way, perhaps with the exception that the collector comes before there is time to cool the milk off. It is then placed in a wagon and carried from one to seven or eight miles to the depot, by which time the milk is thoroughly shaken up and the temperature has risen several degrees. If the car starts from this place the milk may be put on and iced immediately; otherwise it must wait until the train comes along, and reach a still higher temperature. When on board the cars, it is iced, and by the time it has reached the city, from eight to ten A. M., the temperature has been reduced to 50° F. or 45° F. It is then taken from the car to the milk stable, where it remains usually from one to two hours before it is prepared for the consumer and iced. In the mean time the temperature has risen several degrees. The milk remains in the ice chest until two or three o'clock the next morning, when the temperature has been again reduced several degrees. It is then loaded on the wagon and delivered to the consumer. If there is any left over it is taken home, iced, and used the next day. This milk, therefore, is from twenty-four to thirty-six hours old before it reaches the consumer, and what is left over has twenty-four hours more added to it, and still people wonder why milk does not keep longer. This is the supply which reaches the city from eight to ten A. M. There are cars which reach the city from one to three A. M., which bring the milk of the night and morning before; a part of this is used the same day, but most is not used until the following day. It therefore may be used twelve hours fresher, but oftener twelve hours older, than that reaching the city earlier in the day.

As this milk comes from so great a distance it does not pay to carry out brewery grains or refuse vegetables from the markets. The cows are fed on such fodder as is raised in the nighborhood and on meal or shorts. But the milk dealer in the city is so far from his source of supply that he knows but little or any more about the cows or the condition they are in, or upon what they are fed, than the person who uses the milk.

The producer of the "out-of-town milk," being nearer the city, receives more for his milk, which, together with the extra risk of miscarriage from the effects of feeding on brewery grains, makes it about an even thing with him whether he changes his cows once in twelve or eighteen months, or has them "come in" in that time. This milk is from new milch, farrow, and springer cows, and is produced to a great extent from brewery grains; it receives very nearly the same care as the "railroad" milk until it reaches the stable of the dealer instead of going to the depot. The driver of this team starts from twelve to one o'clock A. M., which makes it impossible to bring in the morning's milk, and as the milking is the last chore at night, but few of the out-of-town men raising their own milk, and the dairies being scattered, milk is usually collected in the morning for the next day. It will be seen that the "out-of-town" man may bring in the milk of the night before, but as a rule does not; it is usually from twenty-four to thirty-six hours old. As the "out-of-town" man goes home in the heat of the day, often reaching it at three or four o'clock, it is impossible for him to keep his surplus over. He has a certain poor neighborhood where he skippers his surplus milk, that is, sells it on the street, or from door to door, from a third to a half less than the usual price, often making up the difference with water, and the poor will buy it because it is cheap, though not so good. Several years ago, when milk was selling for eight cents per quart, I knew one man who used to make his extra milk one half water, and sell it for five cents per quart, thus making a "good thing" of it.

The milk raised in the city should be divided into two classes: first, that from cows kept to produce milk for market; and, second, that of cows kept for family use. The first class is found near breweries, or near the salt marshes, and to a great extent the food is brewery grains and rotten potatoes, or other refuse vegetables. Many who have cows keep a team to haul brewery grains and go around the market and collect refuse vegetables. The Milk Inspector, in one of his reports, mentions finding rotten potatoes in a milk stable, but as he did not find the cows eating them did not consider it a case with which he could interfere. This milk may be, and often is, delivered to the consumer warm from the cow, but is thinner in quality, and will not keep as long as milk from cows fed on whole grain, grass, or hay. In fact, the milk partakes to a great extent of the substance on which the cow is fed. The dealer realizes a good price for his milk, and can better

afford to pay twenty or twenty-five dollars difference in changing his cows than to keep one three or four months that is giving little or no milk. This milk is produced mainly from new milch cows, farrows, and light springers. It is the custom with this class of milk producers to buy a new milch cow and keep her farrow a year or more, and then get her with calf, which gives her a more suitable plumpness, by which means she is disposed of with better advantage to the butcher.

The second class of city cows are those kept for family use, usually well fed, and often overfed. A person wishing a cow for family use, not being posted in the market and no judge of a cow, usually pays a high price; if he is fortunate and secures a good one, he receives a good supply of rich milk. If he keeps a daily record of the amount of milk obtained, he will find that once in about three weeks there will be a time, sometimes affecting three milkings, that the cow will not give more than one half or two thirds as much as usual, and that after each one of these turns there will be a gradual decrease, until at the end of a year she will not give one half as much as at first, and that not nearly as good. Not giving much milk, and constantly giving less, she must be disposed of for beef at a loss, or, if the owner wishes to keep her and have her come in once a year, he must have her got with calf three months after she has come in, when the milk will decrease in quantity as well as in quality. To sum up, the owner of a cow under these circumstances is sapping the milk which he intended for his family for six or seven months, and going without for two or three months, for the purpose of getting his cow to give milk again and producing a calf, which, although the material he has consumed, if devoted to milk, would be worth a great many dollars, will scarcely bring a dollar, and often has to be given away. Besides this, the owner has to run the risk of his cow's coming in in bad shape, or of miscarriage. There is no domestic animal so liable to accidents of this kind as the cow, owing to her being milked, a disadvantage which no other domestic animal labors under. In such a case she will give little or no milk.

What I propose as a means of improving the quality of the milk, and at the same time reducing the cost of production, is the spaying of cows for milk, an operation but little known even among veterinary surgeons. After two years' experience and inquiry I have been unable to find any one in Boston familiar with the operation. It consists of removing the ovaries from a new milch cow, which takes away all desire or ability for reproduction, and makes of her a constant milker ever after. These are some of the advantages gained by the operation: first, an increase in the quantity of milk, as the animal has nothing else to do but give milk or grow fat, and by giving milk-producing food the quantity may be increased a third. Secondly, the certainty of having a constant supply of milk of the same quality. Thirdly, producing a richer milk and of even quality, as the animal is always in the same condition, all causes of change having been removed; this alone is inestimable in its advantages to the sick, or delicate children. Without this operation milk obtained from a new milch cow under the most favorable circumstances will vary much; once in three weeks there will be a time often affecting three milkings that the milk is at fever heat, and will not keep as long by one third as when the animal is in the ordinary condition. It is not an uncommon occurrence for a person in delicate health, or a child, fed on a milk diet, although the milk be from one cow, and the greatest possible care taken of it, to have a bad day or a feverish night, for which no reason can be assigned, but which may be traced to such a cause as this. Fourthly, decrease in the cost of keeping, for by the operation causes are removed which produce waste of material that now goes to milk. Fifthly, by this operation cows may be kept for years, giving the same quantity of milk, thus avoiding the loss sustained while the cow is dry and the liability to accidents during calving. Sixthly, the spayed cow fattens more easily, its flesh is better than that of the ox, more tender and more juicy; indeed, no one is ignorant of the fact that all domestic animals, female as well as male, deprived of their procreative organs, fatten more quickly than those that retain them, and the flesh of the spayed female is more tender and juicy than that of the male. By this means the farmer will realize a better price for his cows when they have passed their days of usefulness as milkers, and the public will be protected from a practice often resorted to by farmers to obtain the best possible price for old cows, that is, to bring them to the bull, intending that gestation should give them more suitable plumpness, so that they may be disposed of to better advantage to the butcher. The result of this is mere bloated, flabby flesh, which easily taints; broth made from it is not rich, and is without flavor.

I first became interested in this operation early in 1880, through information obtained from a work translated from the French. I afterwards obtained other treatises on this subject, and soon became convinced of the advantages to be obtained by it. I made inquiries among veterinary surgeons, but could find none familiar with the operation. While making inquiries upon this subject I learned that Hon. Josiah Quincy had had the operation performed at his farm in Quincy nearly twenty years ago. I was told that it was a failure. To ascertain the facts in the case, I called on him at his home. He told me that spaying was performed under the direction of his foreman, and that although he lost a number of cows by the operation he considered it a success, and of great benefit to both the producer and the consumer of the milk; that the cows continued to give a large quantity of milk for a number of years, and that the milk was of a superior quality. It is by his permission that I refer to this. He also informed me that at one time he thought of publishing an article calling the attention of the public to the advantages of this method of producing milk.

My experience teaches me that it will increase the flow of milk and also improve the quality, and that although there will be a slight decrease at the end of a year, the daily average will be equal to that given at the time of the operation. I have one cow that was spayed in November, 1880, was then giving ten and one half quarts per day, and now, after nineteen months of constant milking, nine and a half quarts, and she now comes to the barn every night with milk flowing from her bag. To make a comparison: I have talked with those who have had a longer experience in keeping cows than I have. They all agree that this is a liberal estimate: a cow giving fourteen quarts of milk when she comes in is an extra good one; that at the end of ten months (she coming in once a year) she

would not be giving more than three or four quarts, and that not suitable for use, at which time she should be dried off and not milked the other two months; or that an average of nine quarts a day for ten months and none the other two months is all that could be expected, and that this result can be obtained only under the most favorable circumstances. This would give 2736 quarts. Now I claim that under this operation a cow giving fourteen quarts may be made to average that for three hundred and sixty-five days in the year, as she would increase enough after the operation to make up for any slight shrinkage at the end of the year, making 5110 quarts against 2736 and also better milk.

I do not wish to lead any one to think that this operation is without risk, but after two years of practical experience I am convinced that the risk, when the operation is properly performed, is less than in ordinary cases of calving.

A YEAR'S EXPERIENCE IN TRACHEOTOMY.

BY GEORGE W. GAY, M. D.

DURING the year 1883 I performed tracheotomy twenty-one times for croup. Eleven patients recovered. All but one, a fatal case, were treated in the City Hospital. The cases were not selected, every one coming under our charge being operated upon if requiring it.

Many of the patients had diphtheritic croup, a few membranous, and, occasionally, it was not easy to make an exact diagnosis. Cases presenting enlarged glands and a nasal discharge early in the disease were undoubtedly diphtheritic. On the contrary, cases beginning as an ordinary cold, with no membrane visible in the fauces, no septic symptoms, but having a severe and constant dyspnœa, were called membranous croup. It is not of the utmost importance that much time be spent in discussing the difference between the two varieties of croup, considering the fact that both are extremely dangerous to life, and that both demand essentially the same treatment. Suffice it to say, that all of the cases presented severe and continued dyspnœa, due to an acute laryngeal obstruction of from one to five days' duration.

One patient was twenty-four years old (died); the age of the others varied from eleven months to nine years; a majority were four or five years old. The youngest who recovered was three.

The duration of the disease at the time of the operation ranged from one to eight days; the dyspnœa from one to five days. As a rule the shorter the period of obstructed respiration the more favorable the result.

No ether was used in eight cases, and only a few whiffs in the others; merely enough being given to partially control the struggling and fright. Generally the patient had rallied from the anæsthetic before the tube was secured in its place.

Two children died of shock and septicæmia a few hours after the operation; the other fatal cases survived from two to five days. None died from hæmorrhage. Death resulted from either bronchitis or blood-poisoning. Every case but one derived more or less temporary relief from opening the trachea, and, so far as I know, no life was shortened by the operation. The upper rings of the trachea were usually incised, and also the isthmus of the thyroid, if necessary. In a baby lately operated on at the age of nine months the cricoid cartilage was divided with the result of greatly facilitating the introduction of the tube.

Venous hæmorrhage was quite free in many cases, but no trouble was ever experienced from blood getting into the bronchi. By inserting a tenaculum or hook into the trachea just below the cricoid cartilage and lifting it up the windpipe is under control, and it is not necessary that the rings be exposed before they are divided. At all events I have not found it to be so in many of my later operations. Beginners, however, had better see the rings before they cut them. The tube having been secured by tape, a piece of cotton flannel spread with cosmoline is placed between the plate and the skin to prevent irritation.

After Treatment. Milk, ice cream, and beef tea were the favorite articles of food. Nourishment was also administered by the rectum. Alcohol was never given unless the patient exhibited symptoms of marked exhaustion, when champagne was added to the diet. Several of the successful cases received no liquor during the treatment. Quinine and aromatic spirits of ammonia were given in every instance, while iron and chlorate of potash were not resorted to.

Next to nourishment, I consider *steam* to be the most important part of the treatment. It is conducted from the radiator through a rubber tube, and directed upon the neck of the patient. The vapor is warm, moist, and does not condense in sufficient quantity to saturate the clothing. Atomized or medicated liquids are not used at present. Lime water often produced a disagreeable erythema of the face, and thinking that possibly it might act as an irritant to the air passages, pure steam was substituted, and so far it seems to act as favorably as did any of the sprays formerly in vogue.

In all cases the patient received steam half the time, while to the more serious it was constantly supplied. The very great benefit derived from breathing the warm vapors was demonstrated beyond a doubt in many instances. Under its use the secretion would soften, the respiration would become easier, the child would become quiet, and fall asleep. The importance of a constant and generous supply of steam cannot be overestimated in this affection.

In the favorable cases the tube was worn from six to fifteen days; the average time being nine days and a half. I have found the most satisfactory way of getting rid of the tube to be as follows: At the end of a week, if the respiration is free, the tube is taken out quietly, and the child is let alone. No trials are made to see if he can breathe through his mouth. As the tracheal wound contracts natural breathing through the larynx is gradually restored. With one exception this plan has worked well. In the case of a little girl, after the tube had been taken out, occasional attacks of dyspnœa would come on, which were relieved by the nurse's opening the wound with the dilator, and turning on more steam. The child soon learned to call for this instrument whenever she felt an attack approaching. The use of the tube was not again resorted to, and in a few days the dyspnœa ceased, and the patient recovered.

I cannot close this paper without calling attention to the very great importance of having intelligent, skillful, and devoted nurses in charge of these patients. Two sets are necessary, one for the day and another for the night, and they should have received special instruction in taking care of the tube, and also in re-

moving or replacing it in an emergency. I cannot but feel that my success during the past year was due in no small measure to the admirable care which the patients received from the nurses of the hospital training school.

RECENT PROGRESS IN THE CONSTRUCTION OF INSANE HOSPITALS AND MANAGEMENT OF THE INSANE.[1]

BY WALTER CHANNING, M. D.

CARE OF THE CHRONIC INSANE.

This is a subject which every year thrusts itself more and more on the public attention, and must continue to do so for some years to come. The opinions of alienists have been very different in regard to it, but they are gradually becoming more harmonious. Experiments of various kinds have been tried, the Williard plan proving the most successful, but not always the most practicable.

An often-proposed plan, now meeting with especial favor because of its expediency, so dear to the public heart, is that of the erection of additional buildings in connection with existing asylums. The last report of the Board of Health, Lunacy, and Charity [2] considers our present hospitals too large and too much occupied by the incurable insane to furnish the best treatment for curable cases. The Board favor the erection of small hospitals for the particular treatment of recent cases, leaving, it is to be inferred, the present hospitals filled with the chronic cases. Dr. Earle, superintendent of the Northampton Hospital, has recommended the building of a small hospital on the land owned there by the State.[3] The site spoken of is excellent, and the plan looks feasible. In Dr. Earle's opinion if there were no insane hospitals at all in the State it would be well to build ten or twelve small ones, judiciously scattered about the State, instead of the five large ones we have at present.

The "annex," as he would call the small one to be connected with his present hospital, would be about a quarter of a mile distant. It would have no independent barn, stables, laundry, etc., but would otherwise be erected like an entirely separate institution. The effect would be to give the hospital "the combined advantages of both a large and small institution."

In the "annex" the recent or curable cases should be treated, while the incurables would be cared for in the old hospital building.

At the Connecticut Hospital for the Insane the *chronic class* have been provided for in a supplemental building [4] for two years, the plan being the reverse of that recommended by Dr. Earle. This experience convinces Dr. Shew, superintendent of the hospital, that the plan of supplemental buildings is the true solution of the problem of how best to provide for the chronic insane. Dr. Godding has adopted the same plan at the Government Hospital for the Insane at Washington, D. C., and the State of Illinois has adopted it at Jacksonville.

Dr. Shew has found his supplemental buildings so successful that he wishes for another in which to place the sixty-seven epileptics now in the hospital under his charge.

Dr. R. S. Dewey [5] in a paper read last September before the Conference of Charities urges the adoption of the separate building plan for all classes of the insane. Among other arguments he presents is that of greater cheapness. Every State, he says, with 1,000,000 inhabitants has now, or soon will have, 2500 insane persons to provide for. The average cost *per capita* of the congregate or linear hospital, will be $1000, or $2,500,000 as a first appropriation for buildings alone. On the other hand, very good and substantial detached buildings, generally two stories in height, have been erected for sums varying from $200 to $500 per patient, or about one third the cost of the congregate asylum *per capita*.

FORCED FEEDING OF THE INSANE.

For a number of years, as well as at the present time, one of the fundamental principles in the treatment of the insane has been the administration of the most liberal nourishment, both in quality and quantity. Dr. Clouston has recently called particular attention to the subject.[6] He has given enormous quantities of eggs and milk, often a dozen of the former and six or seven pints of milk daily. This is an excess of nourishment, as he would formerly have thought, and even now food must be given in a hap-hazard sort of way, but he has seen patients gain two or three stone in weight, and acquire nervous stability, on the liberal diet he speaks of.

In America the subject of properly nourishing the insane by force, if not otherwise, was incidentally considered at the meeting of the superintendents of American Hospitals for the Insane, held in 1883. At this meeting Dr. Rogers read a paper,[7] in which he spoke of the need of abundant nourishment in mania and melancholia. "Food," he said, "may be given by the stomach pump, or nasal tube with a fountain syringe. . . . The will of the patient not to take food or medicine should never be an obstacle to the physician."

Dr. Hurd described at the same meeting in a paper read by him [8] the apparatus used by him in forced alimentation through the nose. This apparatus consists of a Jacques or Nélaton soft rubber catheter attached to the largest-sized Hall's health syringe. The catheter is passed through the nostril and food is injected by pressure upon a bulb provided with a valve.

In the discussion which followed the reading of Dr. Rogers's paper on the Therapeutics of Insanity, Dr. T. W. Fisher spoke strongly in favor of the use of the nasal tube, and said that the patient should be fed three times a day with large quantities of nutritious, liquid food. He had recently had very favorable results in nearly a dozen cases. In several he thought life was saved by the artificial feeding. Dr. W. W. Godding thought that it was almost criminally wrong to allow a patient to remain for more than a short space of time without food. Dr. J. W. Draper believed in the necessity of forced alimentation. Dr. W. B. Goldsmith thought that a large amount of food was necessary in acute maniacal excitement, but in melancholia with stupor and less

exhaustion and waste, he thought a fourth as much nourishment would be sufficient. His practice was to put a patient in bed while he was fed with a tube, as his circulation and general nutrition would then be better. Dr. Catlett thought it best not to feed too soon, but ultimately if necessary. Dr. Hill used both the nasal and stomach tube in feeding, but tried moral suasion with patients first. Dr. Gale used the nasal and stomach tubes, but resorted to every other device first. Dr. Steeves thought it easy to fall into a perfunctory habit of using the tube, and continuing its use too long. A patient may at any time be induced to take food, and various expedients should be resorted to to restore the habit.

The above and other members of the Association spoke on the subject of administering food to the insane. The articles chiefly recommended to feed with were milk and eggs, sometimes beef extract; combined with these things stimulants and tonics.

An elaborate and interesting contribution to the same subject has appeared in recent numbers of the *Archiv für Psychiatrie*, etc., by Dr. F. Siemens, Director of the Provincial Lunatic Asylum at Ueckermünde.[1] In the last number he says refusal of food by the insane is often a symptom of diminished tissue change and lack of assimilative power, and in such cases feeding should not be pushed too far. It is questionable if forced feeding attended with struggles and exhaustion on the part of the patient does not do more harm than the food does good. Melancholic patients with stupor are like animals dormant in winter, and a lessened amount of nourishment makes little difference to them.

The abstinence from food in typhoid fever is interesting as bearing on the question of nourishment for the insane. In this fever we see a patient live for weeks on almost no nourishment. From the investigations of Chossat it appears that until forty per cent. of weight has been lost life does not become extinct, and taking the supposed daily loss of weight, it would require a period of eight weeks in an average case of fever before death would ensue from this cause. The elevation of the temperature in the fever, a product of the combustion of tissue, would appear to be a means of prolonging the life of the emaciated patient. Cohnheim has said that *die febrile consumption als unmittelbare Todesursache keine zu grosse Rolle spielen.*

Numerous cases are to be found scattered through the writings of various authors, of prolonged abstinence from food. Among these are Falret's case of a forty days' fast; Wiegand's case of an insane person who lived for sixty-three days without food. Sondèn described a case in which only snuff was used for three weeks, and then for a period of thirty-five days nothing but water. The patient continued the entire time fresh and cheerful, although "sein Bauch ganz und gar einsank." He finally began to eat ravenously, and without the least injury. Bourneville's idiot fasted for twenty-eight days, during which time he had no passage of the bowels, little urine, no vomiting, fever, or pain. When three years old he fasted for three weeks, which seems to show that mentally defective children can endure abstinence better than healthy children.

Stolz, and later Schlangenhausen, described a remarkable case in a Tyrolean insane asylum. The patient was an old woman. She weighed, on admission, one hundred pounds, having previously fasted at home. She was fed artificially, but her weight sank to sixty-six pounds. She then fed herself, and her weight increased to ninety-six pounds. According to Schlangenhausen she was twenty-three years in the institution. She was fed with the tube 12,037 times, and for an unbroken period of twelve years, and her weight fell off to fifty-four pounds. She became scorbutic, lost her teeth, etc.

This case shows the extraordinary tolerance of this patient in regard to a great degree of inanition, and the existence of all the unfavorable conditions which the believers in forced feeding say are avoided by this process.

Dr. Siemens' investigations led him to give up forced feeding except in the rarest cases of injury or paralysis. Unwilling patients were fed with a spoon, but if they objected by closing the teeth, crying, etc., even this was given up. The means of giving food relied on consisted in keeping food constantly either where it could be given to the patient or he could get it himself.

A special department was fitted up in Dr. Siemens' asylum, with nurses day and night, and every wish or whim of the fasting patient was gratified at the earliest moment. After a long-continued fast the patient was put in bed. Little rooms were arranged where the patient could be alone with food. On the window-seats, or on little tables by the beds, food was placed. In cupboards tea and coffee were to be found, as well as raw and cooked eggs, fruit, wine, etc. With these very thorough arrangements, and the greatest care on the part of officers and nurses, Dr. Siemens allowed his patients to go for many days without food.

He details fifteen cases in which patients went for long periods of time without food. Case IV., for instance, of dementia paralytica, went once nine days, another time fourteen days, without food. Case VIII., of melancholia, abstained thirty-three days, with slight interruptions; loss of weight thirty-three pounds. Another time fourteen days, with thirteen pounds loss of flesh. Final result, complete recovery. Case IX., of mania, fasted absolutely for thirteen days; loss of weight fourteen pounds. Then took food regularly for twelve days. After this fasted for thirty days, taking water, however. Loss of weight the second time twenty-seven pounds. Final result, improvement.

Dr. Siemens ends his paper with twelve conclusions, some of which have been briefly indicated above. The fourth conclusion is especially interesting. This is as follows in substance: Voluntary abstinence, from purely psychical causes, is followed by no grave symptoms, either mental or physical, provided the period of abstinence does not exceed fourteen days without water, or fifty days with water, and the loss of weight does not exceed forty per cent.

PROCEEDINGS OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.

ALBERT N. BLODGETT, M. D., SECRETARY.

SPECIAL MEETING.

FEBRUARY 27, 1884. Meeting called to order at eight o'clock, DR. ROBERT T. EDES, Chairman, presiding.

The CHAIRMAN announced that Dr. Morris, of Philadelphia, who was expected to present an essay, was detained by sickness and would not be at the meeting. Dr. H. O. Marcy, however, had received the paper from Dr. Morris, and would read it. The title of the essay was

THE MILK SUPPLY OF LARGE CITIES.[1]

The paper was attentively listened to, and on its conclusion an interesting discussion was opened by

DR. H. J. BARNES, who said: Personally my experience with the milk supply of Boston has provoked the greatest indignation. It begins as a producer on my father's farm sixteen or eighteen years ago, when we, in common with our neighbors, were in a continued state of irritation by what seemed unfair treatment by the contractors. The violation of agreement as to what they would pay for the milk of a stated season, the sending back of sour milk, usually with the cream taken off, the necessity of holding the milk ourselves when at certain seasons the contractors found they had engaged more than they could dispose of, were among the causes of trouble, which continue to the present time, judging from the expressions of views at the recent largely attended meeting of producers in Boston, and from the following letter just received from a milk producer: —

"The contractors hire the car, and although obliged to carry milk for private parties, yet they generally dictate terms, so it is almost impossible for producers to get at the consumers direct. Twenty-seven cents per can of eight and a half quarts, or three and three seventeenths cents per quart, is what my neighbors have had thus far this winter. This month one cent more per can, or three and one fourth cents per quart, while consumers, some of them at least, pay eight, and get extended "topped" milk at that. Producers are compelled to keep a part of their milk at home in order that these cormorants may supply to the good people of Boston milk watered and skimmed, with other abominations thrown in. Right glad would the producers be to send their milk direct to the consumers, if it were possible, but now it must go through the same old channel."

There is an inevitable variation in the supply and in the demand for milk. The farmers dispose of the milk to contractors who make a price for a certain time and agree to take all the milk the farmer produces. Often the quantity is much in excess of the demand and the contractor frequently breaks his bargain with the farmers, who then are obliged either to accept a smaller price for the milk or to make butter or cheese in order to utilize the surplus.

The laws of trade ought to regulate this matter, but if a farmer withdraws his dairy, and attempts to make butter he is met in competition by the manufacturers of oleomargarine, and it does not pay to make honest butter. One of the most objectionable features in our system of supply is the custom of holding the milk in Boston. In many instances milk produced in the morning is taken to the car in the evening, and transported to Boston during the night. The next forenoon it is delivered to the distributers, who take it to their barns or sheds, and there put it in the small service cans for delivery the next morning. It is then forty-eight hours old, sixty before the last meal of that day, and seventy-two hours old before a fresh supply is obtained. Except with the greatest care milk will not keep in good condition this length of time, and I am informed by men engaged in the business that it is common to use chemicals for the purpose of preserving it. The advantages of holding it this length of time accrue wholly to the milkman, for it gives time for "topping," so called, which means the rising of cream, rendering its easy separation from the milk possible, and how often this condition of the milk is taken advantage of we are informed by the analyses of the State Board. It had become a "recognized industry" among the milkmen. The milk should be delivered to the consumer on the day of its arrival in Boston.

As a consumer in Boston my experience has not been less exasperating. During the first few years of my practice I endeavored to employ cow's milk as a substitute for mother's milk, but always with indifferent success or failure, which necessitated its final abandonment. The paper of Dr. Lynde, read before the State Society, prompted me to try its use once more, and this time on my infant daughter. It soon provoked a diarrhœa, and after floundering about with the trial of a number of artificially prepared foods condensed milk agreed with her, and this was used until going into the country, where I obtained a supply of pure cow's milk, upon which she continued to thrive. Returning to Boston I engaged milk of a friend (?), who said he would give me pure milk, but the child soon showed the effects of the change in the quantity of water eliminated. It was impossible to keep her otherwise than in a constant state of irrigation, but not until a diarrhœa ensued, followed by intestinal catarrh, was the milk abandoned, and then only to be tried several times during the winter, again, each time, provoking disturbance of the digestive organs. Setting the milk for cream revealed the fact that it was regularly and systematically robbed of the cream. The following summer my child took cow's milk in the country, and did well. The next fall I made another change, after a long conversation with the new milkman, the substance of which was that I wanted "straight milk," as the life of my infant depended upon it. This he engaged to furnish, but, if possible, it was poorer than any I had ever before had. Although of the color of Jersey milk it had scarcely a trace of cream, and I went to the office of the city milk inspector to see what I could do about it. I was there informed that much of the complaint of adulterated milk was groundless, but if I wished to prosecute I should have the assistance of his office, but that "the department labored under great embarrassment for the want of a horse." I did not see fit to involve myself in litigation, and wrote to the milkman never to show himself on my premises again except to obtain a settlement of accounts, but up to this day he has never sent a bill. I then engaged milk which, I am happy to say, is of sat-

[1] See page 315 of this number of the JOURNAL.

isfactory quality, and my baby is doing exceedingly well with its use.

I trust and hope the influence of this Society will be exerted in support of the State Board in prosecuting these ungodly men, who by their wickedness compromise the health and lives of our little ones, an expression you will not think too severe when you remember that of the samples of milk analyzed by the Board in Boston ninety per cent. were found to be adulterated.

In regard to putting the milk in glass jars, I am informed by Mr. Burnett that after a trial of one year he found it impracticable. The breakage amounted to a loss of $150 per month in a supply of four hundred quarts a day. He now uses large steel cans holding sixty gallons, and is enabled by their use to deliver the milk to consumers but twenty-four hours old, and this is certainly an advantage and would be a great improvement in the system of distribution of railroad milk.

A gentleman doing business in the way of supplying milk to the consumers in Boston, and a member of the Milk Producers Association, who was present at the meeting by invitation of the Secretary, spoke as follows: —

This question naturally divides itself into three distinct parts, the production, the transportation, and the city delivery. Let us first look at the subject from the stand-point of the producer. He may be a wealthy man, perhaps living in or doing business in the city. He owns a farm for the fun of it, and because he must have a way of providing a summer residence for his family. He buys first-class stock, hires men to do the work, makes a large quantity of milk, which is very likely not to be of a superior quality for the reason that all means possible are taken to produce a large flow of milk, and from the lack of personal supervision of the men who do the work. This is the class of men who are agitating all kinds of innovations, putting fancy names on their farms, and a team in Boston to sell their supply, which they add to if necessary by purchases from neighboring farmers. It is possible for them to find ways of disposing of it to personal friends in the city, and others who are led by judicious advertising or the desire to see a new thing succeed. That these methods are not business like is proved by the fact that there is hardly one genuine success in the large number who have at various times attempted it; and no opposition is feared so little by the trade as that from a farmer who undertakes to sell his own supply.

Next we find a large class of farmers who are not rich men, who are farmers because they must be; they may own their farms and stock clear, and may have business talent enough to read the papers, buy their grain at the right time, and dispose of their products to the best advantage. Milk being by far the most desirable of these products they naturally make all other interests subservient to it. Such men have from eight to twenty cans per day, give their personal attention to it, take pride in their reputation, and are a reliable source of supply. As such, they are in great demand, not only among the contractors, but the milkmen themselves, who maintain a jealous watch lest some one more favored by the contractor shall get what they esteem to be their best dairies.

A very general impression has gained ground from misrepresentation and ignorance, that the farmer is the victim of an immense monopoly from which he has no escape. Nothing can be further from the truth. Imagine one man, as described, with eight or twenty cans of eight and a half quarts each to sell. He can hardly be so located within thirty miles of Boston that he cannot choose to which of two or three contractors he will sell his milk, to say nothing of butter makers and creameries. If he is so near the car that he can deliver it himself so much the better for him; if he is not, a team belonging to some contractor will either pass his house, if on a main road, or if not he can carry his milk out to the corner of the main road, where it will be taken up as the collector passes. He receives a certain price for his milk delivered at the car, and the rates vary from one to two, or in some cases two and a half, cents per can for the carting, the collector being able to do the work for the minimum rate because he goes loaded, few farmers preferring to hitch up and drive three or four miles for sixteen to forty cents. If for any reason one farmer desires to be independent of the contractor, he can, as many do, make butter, or if he does not wish to do that, he can come to Boston and find a milkman who wishes also to be independent, and they having traded, notify the contractor, who is compelled by law to freight the milk, the price being regulated by the Railroad Commissioners.

A third class of farmers are those who keep only one or two cows and make a small quantity of milk, who never become an important factor in the problem. All these various producers raise fruit, vegetables, grain, and hay, and expect, if they sell them, to be subject to the law of supply and demand, and to be able to receive only so much as is the ruling price on the day the sale is made; but when we look at the milk question we find a very different state of affairs. Our farmers appoint a meeting of a committee from their number who consult on the price to be established for six months from April 1st to October 1st, or from October 1st to April 1st, as the case may be. The stipulations are that the contractor shall take all the milk produced for six months at a price which he is expected to name in advance, and pay for the same by the 15th or 20th of the month succeeding the delivery. He, using his best judgment, establishes such a price, and agrees that it shall not be changed except with the consent of the above named committee. When all the facts are considered it is not to be wondered at that mistakes are sometimes made. Has he a remedy? Let us see. The summer of 1882 was very hot and dry in August and the first of September. The price was arranged on a basis of forty-three cents per can at the cars in Boston. From September 20th to October 20th it rained a little almost every day, the fall feed was a marvel, the cows gave more milk than in June, and seventy per cent. of the milk that came to Boston was enough to supply the entire demand. The farmers added all the new-milch cows to their herds that could be bought, sold all their calves, and literally flooded the market. January 1st, after three months of ruinous business, the price was lowered three cents per can, trade was stimulated somewhat, and the supply was not in such a tremendous excess of the demand; but the six months' business was a disastrous one, owing to the mistake. On the other hand if butter had been high and grain high, and the fall as dry as the fall of 1883, the farmers would have felt perfectly justified in selling their cows if they wished, or keeping the calves to use the milk, or making butter, and the last thing in the world that would have troubled them

would have been whether the people in Boston were supplied with milk or not. The short-sighted policy of the farmers in such respects, more than anything else, prevents the relations existing between them and their customers being as amicable as might be desired.

How to get cans enough to take all the milk he chooses to produce is the one great trouble every farmer has. The contractor tries to have every milkman furnish cans to take the milk from certain dairies, but has those of his own to send to supply any deficiency. These cans go up on the car dirty, and are left by the collector free of charge; are all of a size, eight and one half quarts wine measure. The farmer, having washed them, strains his milk into them, and puts them into the place he has arranged for cooling the milk. In many cases this is a covered tub or trough near the well or connected with running water from a spring. The contractor or milkman to whom he sells his milk frequently suggests and often helps to pay for this arrangement, which is of vital importance, as upon the care of the milk for twenty minutes after being drawn from the cow depends the value of it as an article of commerce.

How long milk may be preserved by good care and still be as good as fresh milk is a question upon which I would prefer the opinion of scientific men to my own. Certainly experience teaches that it is more desirable to most consumers (if they do not know of the fact) after twenty-four or even forty-eight hours. There is no trouble whatever in keeping it sweet three or four days, if a temperature of 50° F. is steadily maintained, but my experience also teaches that the baker must have as fresh milk as can be obtained if he wants to make a custard of it and get good results. A better cheese can be made from new milk than it is possible to make from that over twenty-four hours old.

The farmers, at their meetings and through the press, are frequently influenced by impractical men, who do not make milk, but who want to seem interested in their welfare, to do away with all middle men, and come directly in contact with the consumer. As before intimated, this has been done in isolated cases, but not yet successfully. Surely if practical men, of years of experience in the business, actuated by every feeling of rivalry and ambition, can see no way to improve the present plan, it is an indication that none can be found.

Let us now look at the second branch of our subject, transportation. Here enters upon the scene the much-berated milk contractor. This system has been the growth of years of experience, and many men have made financial shipwreck in the attempt to fill the position. With the plans and failures of the past we need have nothing to do, suffice it to say the only chance for any profit as it is now arranged is by saving a little here and a little there, by doing a large amount of work for a very small commission, and utilizing the surplus milk so as to make the smallest possible loss. The prices paid in the country as well as those obtained in the city are published, and the commission, about eight cents per can, or one cent per quart, is known to the farmer as well as to the milkman. The Railroad Commissioners, after thoroughly going over the matter, have allowed the contractor to charge six cents per can freight for milk brought thirty miles, which is a very close approximation to the actual cost. Out of this he has to pay freight to the railroad, buy ice to ice the milk in summer, and coal to heat the cars in winter, hire men to load the cars and deliver the milk upon its arrival in Boston, and guarantee it from accident or loss. If he buys and sells the milk he has two cents per can over the six for freight to protect him from loss in the transaction of his business and the surplus milk. As intimated before, he makes a one-sided contract by which he agrees with the farmer to take a large quantity if it is for the farmer's interest to make it, and to get along with a small quantity if the farmer thinks it is not in his interest to make it. On the other hand, he contracts with the milkman to give him just what he wants whether the farmers make it or not. In order to be safe he perforce buys all the milk on a large territory, preferring to manufacture a large surplus into butter to saying to his customers "I cannot supply you, and you must look elsewhere."

(To be concluded.)

THE NEW YORK ACADEMY OF MEDICINE.

LOCOMOTOR ATAXIA AND SYPHILIS.

At a stated meeting of the Academy held March 20th, Dr. Leonard Weber read a paper on the above subject. He commenced by saying that although the pathologist had not succeeded in establishing such a condition as syphilitic sclerosis of the posterior columns of the spinal cord, there had been collected a certain amount of clinical evidence that went to show an apparent connection between syphilis and locomotor ataxia. In a résumé of the history of the subject he spoke particularly of the publication of Fournier in 1876, which was mainly based on statistical data, and which recognized three forms of tabes: (1) the lumbar, which was exclusively spinal, (2) the cephalic, in which the cranial nerves as well as the cord were affected, and (3) the ophthalmic or amaurotic. After alluding to the opinions and researches of other authors, he quoted the remarkable paper of Erb, published in 1879, in which out of 100 cases of tabes reported it was claimed that no less than 61 occurred in syphilitics. When Erb presented his views at the International Medical Congress in London, in 1881, however, they were not received with much favor, and among those Dr. Weber mentioned as distinctly opposed to them were Moxon, Lancereau, Westphall, and Rosenthal. But still more recently Erb has published a second series of 100 cases in which no less than 91 per cent. were syphilitic, while in 1200 patients over the age of twenty-five suffering from nervous affections other than ataxia only 22½ showed a syphilitic history. His conclusion was, therefore, that tabetic patients were very frequently syphilitic, and it was altogether probable that tabes was a syphilitic disease. His opponents claimed, on the other hand, that there was no ætiological connection between the two affections, and that the prognosis was no better in those tabetics who had had syphilis than in those in whose cases there was no such history. After giving statistics from various writers Dr. Weber then referred to the paper of Dr. R. W. Birdsall, of New York, read at the meeting of the American Neurological Association in June, 1883, in which he reported a series of 42 cases of locomotor ataxia with a percentage of only 9½ of syphilitics. In comparing the statistics of different observers, he continued, one could not but be struck by the very

great discrepancy that existed in regard to the frequency with which tabes and syphilis were associated; but it was reasonable to suppose that it was not until quite recently that systematic attention had been given to the matter.

Having spoken of masturbation as a special predisposing cause of ataxia, he said that in all the cases of tabes that occurred in his practice he endeavored to exclude syphilis as a cause, as far as possible, by placing the patient for a time on specific treatment, and as the result of his experience it seemed to him that in certain instances there appeared to be some connection between syphilis and tabes, although it was not such a direct source of origin as rheumatic trouble. From a clinical stand-point there was a great difference between the symptoms in different cases, and great difficulty in ascertaining whether the diseased area was confined to the posterior columns or extended to neighboring parts, such as the lateral columns and the anterior cornua. In syphilitic tabes he believed that other parts were especially liable to be affected. The pathological and clinical manifestations of tabes were protean in character, and it was in the atypical cases that syphilis was most frequently found associated with or antecedent to it. As for the symptoms in general they were the same, as a rule, in syphilitic and non-syphilitic cases. In regard to the prognosis, this was relatively favorable when the syphilitic trouble was not of long duration, and when the symptoms were of irregular character and yielded to specific treatment.

It was a fact worthy of note that the results of antisyphilitic treatment had by no means fulfilled the anticipations formed by those disposed to accept the proposition that tabes was a syphilitic disease. The special treatment that Dr. Weber advised was a thorough course of inunction with mercurial ointment, as well as the use of iodide of potassium and baths. In all his cases of syphilis he had been more successful during the past ten years than during the ten years preceding, and he attributed this to the fact that ten years ago he had given up the internal administration of mercury, as a rule, and substituted inunction for it. While there might be occasional exceptional instances in which inunction would not be well borne, or could not be successfully carried out, he believed that all who would adopt this form of treatment would secure quicker, better, and more permanent cures than in any other way. In case of sudden and threatening outbreaks in old syphilitic patients there was nothing so immediately effective as large doses of iodide of potassium.

Out of 134 cases of syphilis in his practice the central nervous system was affected in 18, or 13½ per cent. In eight of the 18 the trouble was located exclusively in the brain, two of the patients being females and the other six males. In five (all men) it affected the brain and spinal cord both, and in five (one woman and four men) it was confined to the cord alone. Two of the first eight patients had died of cerebral syphilis. The other six were still alive, but not cured. Of the five in whom both the brain and cord were diseased, two had died and five were living, and of the last five one (the woman) had died of syphilitic hemiplegia. Dr. Weber then gave a brief outline of seventeen cases of locomotor ataxia which he had met with in his practice. Three of the seventeen patients had had syphilis, but in one case the syphilis was not contracted until several years after tabes commenced. In the two other cases it seemed to constitute an important ætiological factor. His conclusions were: —

(1.) That there was not sufficient evidence to show that syphilis was a direct cause of locomotor ataxia.

(2.) That there was plenty of proof that syphilis affected the cord, as well as the brain and meninges, and that it might be followed by tabes.

(3.) That such trouble occurred most frequently in those not efficiently treated.

(4.) That syphilitic lesions of the central nervous system were seldom, if ever, cured, and the necessity of early and long-continued treatment in all cases of syphilis was, therefore, apparent.

(5.) That the systematic use of inunction afforded the best means at our disposal for reducing the disease to early and harmless latency.

The discussion of the paper was opened by the President, DR. BARKER, who related three cases of paralytic and ataxic trouble, in only one of which there was a distinct history of syphilis, but in all of which marked benefit was derived from antisyphilitic treatment, though they were not apparently cases of true locomotor ataxia; and he said that he mentioned them simply to illustrate the point that light in regard to pathology was not infrequently furnished by the effect of therapeutic measures.

DR. AMIDON said that he desired to put himself on record as very much opposed to calling typical ataxia a syphilitic disease. This supposed connection between the two affections was based on purely statistical data, but Dr. Birdsall's carefully-recorded cases showed only 9.5 per cent. of syphilitic patients. The fact that the statistics of different authors, as given by Dr. Weber in his paper, varied to such a vast degree (the percentage of syphilitic cases ranging all the way from one to ninety-one per cent.) showed conclusively that statistical inferences were altogether worthless. In addition, the deduction that could be drawn from treatment showed that tabes was not a syphilitic disease. It might be true that a good many cases of apparent ataxia were relieved or cured by antisyphilitic treatment, but he was positive that not a single case of sclerosis of the posterior cords had ever been cured by such treatment. Dr. Amidon then spoke of the pathology of tertiary syphilis, illustrating the subject by a description of the localized and clearly defined cicatricial lesions resulting from the retrograde metamorphosis in gummatous deposits in the liver, and said that the characteristic lesions, affecting uniformly the whole tract of the posterior columns of the cord, were of an entirely different character. In conclusion, he said that the history of the entire course of the disease was against its syphilitic origin, for while its development was very slow and gradual the manifestations of tertiary syphilis appeared suddenly, and were characterized by great activity,

DR. R. W. TAYLOR said that he had already placed himself on record as in accordance with the views just expressed, and he was very glad to perceive the cautious manner in which Dr. Weber had handled the subject. The possible syphilitic origin of tabes had been first hinted at by Duchenne, as he was naturally struck by the fact that in a considerable proportion of cases of ataxia coming under his care he found that the patients had had syphilis. Antisyphilitic treatment proved of no service in these cases, however, and he came to the conclusion that there was in reality no

connection between the two diseases. Until Fournier's publication, therefore, the primary cause of ataxia was sought in sexual excess, alcoholism, gout, rheumatism, and exposure to cold; but when he reported that out of 30 cases no less than 24 were in syphilitic subjects, it began to be suspected that syphilis might be a very important factor in the causation of tabes. Having devoted some time to a consideration of Fournier's views, Dr. Taylor went on to say that in his last work that author had reported 94 syphilitic cases out of 103 tabetic patients. He also gave the statistics of a number of other writers (among them those of Rosenthal, one out of 65), and remarked that in these figures there was certainly sufficient disparity to throw doubt on any conclusions derived from them. In addition, he criticised the manner in which Erb and Fournier's cases were recorded, saying that it was painful to note the meagre and unsatisfactory data which they regarded as positive evidence of antecedent syphilis. As to the matter of pathology, he could only reiterate what he had said in the work in which he had acted as the collaborator of the late Professor Bumstead. Locomotor ataxia was known to be caused by sclerosis of the posterior columns, a lesion exactly limited to this portion of the cord, though often involving it to a considerable extent. The lesions of syphilis, on the contrary, were patchy and less diffused, and, moreover, always originated in investing structures, subsequently involving the cord itself. The same was true of cerebral syphilis, in which the lesions began in the meninges or bones and afterwards induced softening or induration of the brain. It was true that ataxic symptoms sometimes arose in the course of tertiary syphilis; but a careful study of the case would show that the trouble differed in many respects from true progressive locomotor ataxia.

Dr. Birdsall, having stated that he fully concurred in the conclusions of Dr. Weber in regard to locomotor ataxia and syphilis, said that the most of the cases which he had reported in his paper had been under his own personal observation. Out of 42 cases four were syphilitic, a percentage of 9.5, and he was surprised that this result differed so greatly from the statistics reported by Erb and some others. He then repeated the statistics given by various authors, and said that up to the present time, not including Erb's last hundred cases, there had been collected 525 cases, with an average of forty-three per cent. in syphilitics. This number, he thought, however, was entirely too small to base any definite conclusions upon. While, therefore, it would not do to ignore statistics altogether, any deductions derived from them in the present state of the question ought to be received with caution. In regard to Erb's remarkable figures, it might be explained that many of his so-called syphilitic cases would not be accepted as such by dualists, from the fact that he made no distinction whatever between chancre and chancroid, regarding the existence of either as conclusive evidence of syphilis; but if it was really found that there was a syphilitic history oftener in cases of ataxia than in other affections of the nervous system, the idea of a certain connection between the two diseases ought not to be rejected entirely. At the same time he was free to confess that up to the present no convincing proof of the existence of any such connection had as yet been presented. But while the lesions of syphilis in the nervous system were pretty well understood and generally recognized as distinctly different from those occurring in typical locomotor ataxia, the time might perhaps arrive when we should have to recognize syphilis, like sexual excesses, as one of the predisposing causes of ataxia.

Dr. E. L. Keyes thought that on account of the weight of authority supporting the figures the statistical element of the question could not be altogether disregarded. Personally, he did not believe that pure sclerosis of the posterior columns was caused directly by syphilis, but he could not see why it should be excluded altogether as a possible ætiological factor in tabetic trouble. Dr. Keyes had had one or two instances in his practice where ataxic symptoms had been distinctly relieved by antisyphilitic treatment. He used mercurial inunction and the iodide of potassium; commencing with the iodide, and pushing it to the limit of tolerance. In addition, baths were employed, in accordance with the Hot Springs method. While none of his cases had been cured, the benefit received had sometimes been so marked that he was fully convinced of the efficacy of specific treatment in certain cases with ataxic symptoms.

Dr. A. McLean Hamilton thought that the whole trouble in regard to the matter lay in the fact that two distinct forms of disease had been more or less confounded with each other, namely, classic sclerosis of the posterior columns of the cord and cerebro-spinal syphilis. In regard to the former he had found that not more than twelve per cent. of the subjects of it had ever had syphilis. In irregular ataxic cases there was a much larger percentage of syphilitics; and in these he had seen marked benefit derived from the use of iodide of potassium, given in the most heroic doses.

Dr. F. N. Otis said that it seemed to him that we could hardly afford to disregard the experience of such distinguished investigators as Erb and Fournier, however much we might ordinarily be disposed to distrust statistics. In their respective fields these men occupied the most exalted position, and their opportunities for observation and research had been unsurpassed in extent. Although his own personal experience on the subject was small, Dr. Otis said, his knowledge of syphilis in general led him to believe that the disease in question might, perhaps, be of syphilitic origin. As a disease of the connective tissue it acted apparently in the same way as syphilis when located in the testicle or liver, for instance. Having explained the pathological process in syphilis at some length he went on to say that the lines of cicatrization, which were characteristic of the late stages of the disease, were believed by the best authorities to follow closely the lymph distribution of the part or organ affected. When these cicatricial tissues were once formed there was very little hope left of accomplishing anything by way of treatment. He quoted from Erb to show that very little was yet known of the true character of the pathological process in locomotor ataxia, and stated that that recognized as taking place in syphilis would satisfactorily explain all the phenomena observed if it could be proved that the cord was supplied with lymphatic vessels. It was only a short time since the presence of these vessels had been demonstrated in the bones, and it was not improbable that ere long they would be shown to exist here also. The impossibility of removing cicatricial material by any therapeutical measures that had yet been discovered would also account satisfactorily for the fact that ataxia was not, as a rule, benefited by antisyphilitic treatment. That relief was afforded in a certain proportion of cases by specific

treatment, however, was shown by some instances which had occurred in his own practice. In three cases of ataxia marked benefit had been derived from it, and in two of these he had found by the relief which followed the division of a contracted meatus that all the urinary trouble experienced was not due to the tabes alone. In all ataxic cases, therefore, he thought it best to give the patient the benefit of the doubt, and institute a thorough course of antisyphilitic treatment before giving up the case as altogether hopeless.

DR. E. C. SPITZKA said that he thought the question had been looked at from too narrow a point of view, since an important set of facts had been ignored. In secondary syphilis the cerebro-spinal axis was sometimes affected, and it had been shown that in certain instances there was complete abolition of tendon reflex. Why, then, might not this also take place in tertiary syphilis? In his own cases two thirds of the patients had had syphilis, though in none of the only four cases occurring in females which he had had was there any such history. After referring to paralytic dementia as a disease, which, like locomotor ataxia, frequently occurred in syphilitics, he said, in conclusion, that ataxia was not strictly a systemic disease, since other portions of the cord besides the posterior columns were not infrequently affected.

Recent Literature.

The Pathology and Treatment of Venereal Diseases. By FREEMAN J. BUMSTEAD, M. D., LL. D., and ROBERT W. TAYLOR, A. M., M. D. Fifth edition. Revised and Rewritten, with many Additions, by DR. TAYLOR. With One Hundred and Thirty-nine Wood-cuts and Thirteen Chromo-Lithographic Figures. Philadelphia: Henry C. Lea's Son & Co. 1883.

Few American books on medicine have met with greater success than Bumstead's Venereal, and the present edition by Dr. Taylor, whose name was associated with the original author's in the fourth edition, shows conclusively, if such a showing were necessary, that the mantle has fallen upon no unworthy shoulders.

In his preface Dr. Taylor pays a tribute to the memory of his friend and colleague which deserves repetition in speaking of the book which remains as his proudest monument: "No nobler figure is to be found in medical literature. As a man he was broad, genial, and lovable; as an author he was erudite, clear, and concise; and as a physician in his department he was preëminent. As the French can point with pride to their still living Ricord, and the Germans to their deceased Sigmund, so we Americans can point to our Bumstead as the pioneer and master. His friends loved him, he was respected by every one who knew him, and all bowed the head in sorrow when he passed from among us."

The first edition of Bumstead's Venereal Diseases was published in 1861 "with many misgivings" on the part of the author. It met with unexpected success in our own country, and was translated into more than one foreign language. It was not the author's first appearance as a writer, as he had previously edited and translated Hunter's Venereal with Ricord's Notes. The second edition of the Venereal Diseases appeared in 1864, the third in 1870, and the fourth, with Dr. Taylor as coadjutor, in 1879. These various editions show in general the prevailing beliefs at the time of publication among syphilographers, and the series forms a history of the progress of syphilography during the past twenty years. As an instance of the beliefs that have figured largely only to disappear we need but refer to the chapter on syphilization, which, in the third edition, was even illustrated with a full-page outline figure showing the site and date of a very large number of inoculations. In the present edition the subject has shrunk to a scant two pages, and is regarded only as an interesting matter of history. The brain and nervous system, which were supposed to suffer but rarely from the ravages of syphilis at the time of the first edition, now occupy a position of great prominence in connection with the disease, and their consideration fills many pages.

The recommendation of the abortive treatment of gonorrhœa is retained in this edition, and, though guarded, it might quite as well have been omitted. With the abandonment of the belief in a single specific virus in gonorrhœa the principal logical argument for a belief in the efficacy of a substitutive medication is gone. The directions for its use allow it only in one case in a hundred, and never after acute symptoms or scalding have set in. It is not every one who can feel sure of a diagnosis between the slight mucous discharge of a bastard gonorrhœa and the beginning of the more severe form before the scalding appears. Logical as this treatment was to the believer in the specific contagium of gonorrhœa its actual working was unsatisfactory, and its use is condemned by the majority of recent authors, even those who retain a belief in the specific nature of the disease to be cured.

Slight additions have been made to the text which show the present state of belief in regard to the existence of syphilis in animals and micro-organisms as a cause of syphilis.

The growing size of the book has already rendered it somewhat ponderous as a text-book for beginners, for which the earlier editions were better qualified, and has made a place for smaller hand-books which avoid discussions on unsettled questions, and confine themselves to plain statements of facts and principles. At the same time certain things might be pointed out which are by no means fully treated, as the subject of syphilis and marriage, which has a slight mention in this last edition. But after all, after pointing out what one believes to be its sins of omission and commission, after saying that it is too large for a manual and too small for a complete treatise, it remains to repeat what has been said of it in almost every notice which has appeared from the first edition to the present time, that it is certainly the best single treatise on venereal in our own and probably the best in any language.

Bacteria and the Germ Theory of Disease. By DR. H. GRADLE. Chicago. 1883.

This little book contains a series of eight lectures delivered at the Chicago Medical College. There is nothing new or original in the compilation, and it merely adds another to the list of such works, already too long. Its value and the necessity for its publication must be entirely local.

— The students at Edinburgh numbered, last year, 3340. When its new buildings are completed it is claimed it will be the largest university in the world.

Medical and Surgical Journal.

THURSDAY, APRIL 3, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by Houghton, Mifflin and Company, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 Park Street, Boston, Mass.

THE SANITARY CONDITION OF THE SCHOOL-HOUSES OF THE CITY OF LYNN.

We have before us a report of a special committee, of which Dr. J. G. Pinkham was the chairman, appointed to examine into the sanitary condition of the school-houses of Lynn. The city of Lynn being a place of 44,000 inhabitants, occupied largely in manufactures requiring a considerable degree of intelligence, and having, apart from this, every reason ourselves to believe that it is possessed of at least an equal public spirit and appreciation of the advantages of a public school education as other places of its class in the State of Massachusetts, the results of the committee's investigation should present more than a passing interest for parents and for those concerned with school hygiene, especially as one or two points seem to have been worked out by the committee in their report with more than ordinary care. Moreover, the Hygiene of Study, of which we spoke in our last issue, is a vain problem without hygienic surroundings.

We shall confine our comments to the two important particulars of lighting and ventilation, the defects in which, as shown by the Lynn schools, no doubt exist largely elsewhere in this State, and if in Massachusetts, where so much attention has been given to public schools, then probably in a still greater degree elsewhere.

In the matter of lighting the committtee adopt the usual minimum standard of authorities on this subject, which is, that the size of the windows collectively should equal at least one sixth of the floor space or sixteen per cent. Cohn, in Germany, requires a ratio of at least a fifth or twenty per cent.

In Lynn it was found in ninety-one school rooms that the ratio of window surface to floor space was too small, in some being as low as a twelfth, or eight per cent. only. Of the large grammar school buildings only one is reported as well lighted, the percentage of window to floor space being sixteen; in the other buildings this percentage ranges from ten to thirteen, and, we are told, the evil of insufficient light might easily have been avoided in the construction of these buildings had the architects (or builders?) been reasonably well informed in regard to the amount of light required in school rooms.

"Out of one hundred and twenty rooms visited, only three have light from the front; four have windows at the right only; four at the left only; twenty-eight at both sides, nineteen at the rear and both sides. The remaining rooms are lighted from the rear and one side. The middle rooms in two buildings, eight in number, have one window on each side near the back part, so that the light practically all comes from the rear, with reference to the greater number of pupils, — a very objectionable arrangement. In some school rooms with side windows the strongest light comes from obliquely in front of the pupils; as, for instance, in the building on Baltimore Street, where the light from the windows near the rear is cut off by trees. This difficulty could be obviated in a measure by reversing the arrangement of the desks.

"In many rooms the window sills are on a level with, or below, the eyes of the pupils seated.

"One building in particular is arranged on the worst possible plan. Both ends of the building are taken up by entries, shutting out light and air from the four rooms on every side except one. Sufficient light and air are clearly impossible under these conditions. The rooms on the north side, constituting one half the occupied part of the building, are absolutely sunless during school hours."

To the subject of ventilation especial attention was given by the committee, and the report shows a condition needing especial attention. As a standard of purity of air for respiratory purposes, that laid down by Dr. Parkes was adopted, namely, that air containing more than six parts of carbonic acid per 10,000 volumes (.06 per cent.) is unfit to breathe, and that with a ratio of eight, nine, or ten parts per 10,000 the air smells stuffy and close, and beyond this becomes foul and offensive. Accurate analyses of the air of a certain number of school rooms were made by Professor Hills, of the Harvard Medical School, and are given in the following table taken from this report, in which is included an analysis of air from out of doors, taken at the same time. It is fair to suppose that in all the instances given the carbonic acid had no other source than the respired air from human lungs, and therefore represented the measure of irrespirability of the atmosphere.

Place.	Day.	Hour.	Tem. of Room.	Outside Tem.	Carbonic Acid per 10,000 Vols.
Room 10, Whiting School	Nov. 28	11.25 A. M.	72° F.	40° F.	18.15
Primary No. 14, School Street	Nov. 28	11.35 A. M.	70° F.	40° F.	17.05
Primary No. 12, Baltimore Street	Nov. 28	11.50 A. M.	72° F.	40° F.	12.65
Primary No. 33, Chase Avenue	Dec. 3	3.45 P. M.	68° F.	25° F.	29.10
Master's Room, Shep. School	Dec. 3	4.00 P. M.	70° F.	25° F.	17.95
Primary No. 30, Elm Street	Dec. 5	10.28 A. M.	68° F.	41.5° F.	17.21
Primary No. 8, Parrott Street	Dec. 5	11.35 A. M.	68° F.	41° F.	15.17
Master's Room, Cob'et School	Dec. 6	11.30 A. M.	76° F.	41° F.	12.82
Out of Doors. Silsbee Street	Dec. 6	11.55 A. M.	–	41° F.	3.69

These analyses show the air in some of the rooms to be *very bad*, much worse in some instances than that of school rooms in Boston as exhibited in the second report of the Massachusetts Board of Health, and these analyses gave far from favorable results, as

may be seen by the following table giving a portion of the analyses taken from the report of the Board: —

AIR OF SCHOOL-ROOMS IN BOSTON.

Grammar Schools.	Date.	Hour.	Carbonic Acid per 10,000 Vols.
Myrtle Street	March 24, 1870.	10.25 A. M.	13.43

The Lynn school rooms from which air was taken for analysis are said to be representative of the rest, and the reasons given for the condition found are that (1) the cubic air-space allowed to each scholar is too small, making good ventilation without draught difficult or impossible; (2) the means of ventilation employed are, as a rule, wholly inadequate for their purpose, and would be so, in most instances, even if there were much less crowding of the rooms.

The cubic air-space per scholar in the majority of the rooms is reported at less than 200 feet, in some being but little over 100 feet. The inadequacy of such a provision is readily shown by remembering that with the minimum air-space (220 cubic feet) allowed by authorities on hygiene the air would have to be changed seven times every hour to provide even 1500 cubic feet of fresh air per hour, or half the amount held to be necessary for adults. It is extremely difficult to effect the change of the air of a room as often as seven times in the hour without creating an objectionable draught. From one room, that of the Principal of one of the schools which was tested, air was found to be escaping from the outlets at a rate giving a change of not quite once in two hours, the Scylla of a draught having here been avoided for the Charybdis of impurity, or, as is more probable, very little thought having been given the subject.

Even the American brain is still subject to natural laws, and will not perform its functions, much less develop properly, in an impure or poisonous atmosphere, although the too common condition of school rooms and court rooms shows that such expectations are tacitly entertained of it. The Egyptian task-master was far less unreasonable in demanding from bondmen bricks without straw than are our own people in demanding from fellow-citizens and their own offspring sound and invigorating mental labor without a suitable supply of oxygen.

It is hoped by the reporting committee that the evils at Lynn are sufficiently plain to lead to the appointment of a supervisory committee. In these columns we have frequently had occasion to advocate the appointment of health supervisors or instructors in hygiene. We have no prejudices as to the title or composition of the office intrusted with hygienic supervision of schools in cities and large towns, but continue unaltered in the conviction — the expression of which has hitherto, it must be confessed, borne but little visible fruit — that such supervision should be provided and intrusted to special and qualified officers.

THE FOOT AND MOUTH DISEASE.

THE recent introduction of this distemper by means of an importation of some infected cattle into the country at Portland, Maine, its dissemination to a certain extent among neighboring native cattle, its supposed subsequent outbreak first in Kansas, then in Iowa and Illinois, seems to indicate that there exists at this time, among those whose duty it is to prevent just these occurrences, an amount of carelessness or ignorance entirely inexcusable, and which, if continued, will surely lead sooner or later to causes that will in their effects upon our public health and wealth be most disastrous and lasting. To show this let us, very shortly, review facts as reported from various sources.

During the summer of 1881 "under authority conferred by the sundry civil appropriations bill" the Secretary of the Treasury on July 16th appointed three persons upon a commission to be known as the "Treasury Cattle Commission." Of these three, the chairman was a veterinary surgeon, another had practiced as such for a long time, and the third was an editor of a live-stock journal. To this commission, after a time, it came to establish at several of our ports quarantine stations that they might *aid* the government in preventing the importation and spread of exotic contagious diseases of cattle, two of which, specific pleuro-pneumonia and epizootic aphtha, were well known to exist in Great Britain, from whence we were receiving numbers of animals.

The Board labored with this newly imposed duty, and among other results there was established at Portland a "cattle quarantine," to reach which, as we are informed, cattle landing from the steamers must be driven for a considerable distance over a public highway upon which it is possible for them to meet or be followed by other and native cattle without any restraint whatever; and to the actual occurrence of this chance is due the existence of foot and mouth disease among cattle about Portland. If the statements of competent eye-witnesses concerning the methods, or per-

haps it would be better to say the lack of methods, pursued within the "quarantine" are correctly reported, the negligence and stupidity of those in charge of it are almost beyond belief. One instance, as related to us by a person who witnessed the incident, will perhaps suffice to show this sufficiently for present purposes: —

Some imported cattle coming to the station a little time after the diseased cargo, were put by themselves in a barn at some little distance away from the sick ones. Upon a certain occasion it became necessary to have for a little time a few extra men in attendance upon them, and one of the members of the commission, who happened to be present, ordered that certain men who were then in attendance upon the diseased animals be called to come directly and give the required assistance. To this the owner promptly objected, referring the matter to his own veterinary surgeon, there present, who sustained the objection; the order was countermanded, and the blunder prevented.

When it is understood, as it is among all properly qualified men, that the contagious principle of foot and mouth disease is surely and easily conveyed by media, as of clothing, ropes, pails, litter, and the like, one is forced to the conclusion that this unqualified member of the commission had better be superseded by a capable man, or else that the government holds itself fairly open to the criticism of keeping an establishment for the propagation of contagious diseases among cattle. Is it that even this service must be so strangely mixed up with politics and political expediency in this country that nothing but a *show* of action in this direction is tolerated by the authorities at Washington? Or is it, perhaps, that properly qualified men are so few among us that their services for this work cannot be obtained. Let us look at another phase of this same matter.

During the month just passed we were informed by the daily papers, which had received the news by telegraph, that foot and mouth disease was reported by "the United States veterinary surgeon at Fort Leavenworth," who had been detailed to investigate the matter as existing in a certain part of Kansas. In the dispatch there followed such a description of the nature of the outbreak as to lead any one with a knowledge of matters of the sort to decide at once that whatever the disease was it was *not* "foot and mouth."

Rapidly following this outbreaks were reported from at least two other States. Much excitement was worked up, and a large appropriation was obtained to "stamp out" what we were told, a little while after, by another governmental veterinary surgeon, if he is correctly reported, was "ergot in the hay." In view of the rather farcical ending of the whole matter we can this time — if we do not belong to the veterinary profession — afford to smile, but still the more thinking mind will ask itself what the meaning of all this is. In the first place the government has employed an unqualified man; in the second, one who is a graduate of a school in which the total time demanded for professional study is something less than ten months. Perhaps we need look no further. If it is true that the "principles and practice" of veterinary medicine are to be "picked up," or even that the science is to be sufficiently mastered by about nine months of special study, what cause of wonder is there that these mistakes occur, for it cannot be a science of any depth or stability. On the other hand, if it is true that there is a real science of the sort, which can, by being allowed to exercise its proper function, be made to do service in protecting public health and domestic industry, then why is it that a government, which should foster the interests of the people, is so unfortunately advised in this matter?

The general public is beginning to realize how important a bearing the diseases of domestic animals and their control by proper measures resulting from their intelligent study is destined to exert upon the material prosperity of the country. People do not yet appreciate, however, the intimate connection which a more exact ætiology and pathology have shown to exist between many of the diseases of domestic animals and of men. This very foot and mouth disease which has of late been occupying so much attention is an excellent illustration of such connection. An extensive epidemic of aphthous sore throat at Dover, England, having its origin in a dairy supplied with milk from infected cattle, is at this very time under investigation by the medical health officer of the district. That man is liable to contract the disease has been sufficiently proved before.

We do not know how many epidemics, among animals and human beings, nor how much loss must take place before the needed lessons are taken to heart, but fear that the process will be expensive if not slow.

MEDICAL NOTES.

— Dr. D. Humphreys Storer, of Boston, celebrated his eightieth birthday last week, when "honor, love, obedience, troops of friends," found themselves appropriately and happily sheltered beneath his roof.

— The Legislature of Connecticut, in session at Hartford, passed a bill recently prohibiting the sale, for hotel or family use, of any ice cut from waters made impure by sewage, mill refuse, etc. There was no objection in the bill to the use of such ice by market men or others for preserving articles. After a very short debate a member rose with an amendment that the bill should not go into effect until next November. He frankly stated that one of his constituents had a lot of impure ice, and as he had expended his money in cutting and housing it it was only fair that he should be permitted to sell it wherever he could. In spite of the whimsical character of this objection the House, to the surprise of everybody, agreed to the amendment. The Senate promptly concurred, but within the next few days so many indignant protests were received that the Senate, last week, recalled the bill, and struck out the obnoxious amendment.

— M. Jaccoud, in an analysis of a large number of temperature charts in typhoid fever (*Journal de Médecine*, February, 1884), shows that the general impression as to the average date of the attainment of the

maximum temperature in that disease is not correct. Not the sixth to eighth day, but the fifth represented the maximum; in fact it was not very rare for the maximum to be reached on the second day. In the light of these observations it evidently is unsafe to exclude typhoid on the score of having a temperature of 104° F. on the second or third day. The examination of these charts showed that precocity of the fever constituted a rather unfavorable element of prognosis.

— At the "Health Exhibition" to be held in South Kensington, England, in May next, food, dress, the dwelling, and the workshop are to form the staple attractions. The exhibition of food will, we learn from the *Lancet*, be international, and will embrace raw food substances from all parts of the world, and the different methods of preparing food which are in vogue in different countries will be fully illustrated. The storing, conveying, and preserving of food, as well as its adulteration, and the diseases produced by unwholesome food, will all form the subject of exhibits. Educational machinery and the hygiene of the school-room will also form subjects for illustration. Surgeons J. S. Billings and J. S. Brown, United States Army, have been detailed to attend this exhibition. They will also represent the United States Army Medical Corps at the International Medical Congress, which will convene at Copenhagen in August next.

— The question has been raised as to the frequency of epilepsy in the colored race, by the following remark of Dr. Lawson Tait in a discussion as to deafness in white cats (*Nature*, xxix., 164): "Every kind of white animal I have kept as a pet has proved to be the subject of epilepsy; and the association is suggestive, when we are told, as I have been frequently, that the disease is unknown among negroes." In *Science*, February 29, 1884, Alexander Graham Bell, in a communication, denies this assumption regarding the colored race, at least in America. Another writer, in the same periodical, claims that epilepsy is more frequent in negroes than among whites, which claim is apparently borne out by the following table furnished Mr. Bell by General Seaton from the unpublished figures from the tenth census: —

Percentage of epileptics in the United States, 1880, *by race and sex.*

White male	.004749
White female	.003751
Black male	.005011
Black female	.004267
Indian male	.002942
Indian female	.003084
Chinese male	—
Chinese female	.020925

NEW YORK.

— The annual commencement of the New York College of Pharmacy was held at Steinway Hall on the 17th of March. The graduating class numbered seventy-one, and among them there were two young women.

— The projectors of the new cancer hospital have published a letter from the late Dr. Sims in regard to the matter, written a few weeks before his death, in the course of which he says: "A cancer hospital is one of the great needs of the day, and it must be built. We want a cancer hospital on its own foundation, wholly independent of all other hospitals. . . . Its medical board ought to be men who go into it with zeal, determined not only to give temporary relief to human suffering, but to do something toward discovering better methods of treatment. We are now making great progress in every department of medicine. Why should not cancer derive some benefit from this general onward movement? Doubtful points of practice can only be settled in the wards of a great hospital, and success in treatment can only here be demonstrated. We want a medical board of large and liberal views. I would take knowledge wherever it can be found. I would invite any man who claimed to have a specific to come and try his remedies under the supervision of a committee specially appointed for that purpose. I would offer a large premium for any improvement, whether in constitutional or local treatment. I would do everything to obtain practical knowledge on this subject, regardless of the source from which it emanated. . . . Let me beg you to take steps at once to inaugurate a movement which must culminate in a great work so much needed here and now. The subject of cancer is too large and its interests too great to be lodged in a pavilion subsidiary to any other hospital, whether special or general."

Correspondence.

ARTIFICIAL INFLATION OF THE COLON WITH GAS.

BOSTON, *March* 20, 1884.

MR. EDITOR, — In regard to the artificial inflation of the colon with gas, as recommended by Professor von Ziemssen, and mentioned in No. 12 of the JOURNAL, it may not be wholly useless to quote the statement of Austin Flint in his Practice of Medicine,[1] who, in treating of Intussusception, says: "I have known rupture to result from the injection successively of an acid and alkaline liquid, giving rise to the evolution of gas by combination within the intestine." It is also on record that injections of water, given to relieve intussusception, have ruptured a portion of normal intestine, below the displaced part, so that it seems clear that, in clinical experiments, we should keep very far on the safe side of an "enormous degree of inflation" or even "extreme expansion" of the colon. Respectfully yours,

HERMAN F. VICKERY, M. D.

Dr. Flint gives no particulars as to the condition of the intestine to which he refers, nor do his words indicate whether the accident occurred within the writer's personal knowledge or was merely reported to have happened. On the other hand, V. Ziemssen's language is very explicit, especially in regard to the experiments on intestines immediately after death. We should think by following the suggestion as to introducing the acid and alkali in divided portions any danger of rupture would be easily avoided. Water, from its weight, is probably more dangerous than gas. — REP.

Miscellany.

A CONTRIBUTION TO THE SURGERY OF THE BRAIN.

A PATIENT was recently exhibited by Dr. Macewen before the Pathological and Clinical Society of Glasgow,[1] whose brain had been operated on for the relief of left hemiplegia, and who has recovered the power of movement to such an extent as to enable her to walk freely about, though with a paraplegic gait, to raise her arm to the level of her shoulder, and to grasp with considerable power, though there is a deficiency in co-ordination of movement of the hand.

She had a syphilitic history. The hemiplegia was preceded by a tingling sensation and a numbness of the left arm and leg, which increased until it ended (within six weeks from its commencement) in complete motor paralysis and a deficiency in the perception of touch. The left side of the face was also slightly affected. This was accompanied by mental confusion and loss of memory. Full antisyphilitic treatment had been tried along with counter-irritation to the head, previous to her coming into the Royal Infirmary, and while she was in the medical wards of that institution. These did not seem to have relieved in the slightest the condition spoken of above.

Trephining was performed over the middle of the ascending frontal and parietal convolutions. The internal table of the disk removed was found softened and thicker than usual, having on its internal surface a series of projections or roughnesses, some protruding for nearly one eighth inch beyond the general level. A second opening was made over the occipital region, and a similar thickening of the internal table was found. Opposite to the first opening the dura mater was paler than normal, and somewhat thickened. It was elevated, and a false membrane of yellow color, and about one sixteenth of an inch in thickness, was removed. An incision was made into the brain in the direction of the paracentral lobule, when a gush of grumous red-colored fluid escaped out of the opening. Its quantity was not measured, as it could not have been collected. Approximately, there would be about a couple of drachms. The brain pulsations previously were not discernible, but, after the escape of this collection of fluid, it was thought that very feeble pulsations were seen. Some of the surgeons standing by doubted the presence of the cerebral pulsation. The disks of bone were carefully divided into segments and replanted, and are now quite firm. Wounds treated without pus production.

The day after the operation the patient expressed herself as very much better. On the third day she moved her toes. Within a week she lifted her leg from the bed and stated that she was so much better that she could turn in bed, and believed she could walk. The fingers were moved within a week. Her mind greatly changed for the better, her memory improving, and her intelligence becoming much brighter. She can now walk freely about, and does a considerable amount of domestic duty in the ward. She lifts her arm to the level of her shoulders, and can grasp with considerable force.

In the discussion which ensued upon the exhibition of the patient the improvement was attributed to the result of the operation by surgeons who had seen the patient before it was performed. Regarding the division of the disk of bone before its replacement, it was held by one speaker that it was a decided advantage to divide the disk of bone into parts, and he was of opinion that it would be a still greater if the centre of the disk were perforated before dividing it, so as to admit of the insertion of a small drainage tube. Granulation tissue was apt to block up the spaces between the particles of bone and prevent free drainage. Dr. Macewen in closing the discussion said that on two occasions he had introduced the disk of bone entire: one did well; a small portion of the other necrosed, and the whole had is consequence to be elevated. The advantage of having the bone in small pieces was that you could, under these circumstances, easily remove the affected portion and leave the remainder.

[1] Glasgow Medical Journal, February, 1884.

THE SURGICAL ABUSE OF SPONGES AND OF SILVER WIRE.

UNDER the somewhat sensational title of "Seven Surgical Follies," Dr. John B. Roberts (*Polyclinic*, February 15th) considers what he calls the ether folly (the abandonment of ether for chloroform on account of lack of knowledge of how to secure anæsthesia by the former), the incision folly (too short incision), the styptic folly (use of styptics to control hæmorrhage), the adhesive plaster folly (plaster in the place of sutures), the dose folly (inadequately small doses), the sponge folly, and the suture folly. On these last two points he says: —

"What I term the sponge folly is the habit of employing sponges for absorbing blood from wounds, when napkins or towels are always obtainable, and are far less liable to introduce septic material into the wound. Sponges, while too expensive to be thrown away after each operation, are cleaned with great difficulty. Servants and nurses, therefore, not appreciating the importance of thorough cleansing and disinfection, often neglect this duty. Hence I prefer towels, and if I do an operation at a patient's house, always use clean towels obtained there. Thus I secure an almost certain immunity from purulent or septic dirt in the articles used for absorbing blood. Perfectly clean surgical sponges are the exception, but clean household towels are the rule. At the polyclinic I use for this purpose, to a considerable extent, Japanese paper napkins, which are thrown away after being once used. Absorbent cotton is too expensive for such uses, except to a limited extent, and besides, has a tendency to leave filaments entangled in the wound."[1]

Regarding the "suture folly," the author says: —

"I do not refer to the erroneous opinion, long held, that sutures should not be used in the scalp. This tradition has been disproved so often that few surgeons would now hesitate to use sutures as freely in the scalp as elsewhere. What I call the suture folly is the ad-

[1] We learn by a note in another part of the same journal that these Japanese napkins are found by Dr. Roberts as efficacious and clean as cotton ones, and are so cheap that they can be thrown away after being used. They cost from $6 to $7.50 a thousand. The cost of washing a large number of ordinary towels is thus avoided. The paper towels are scarcely suitable for drying hands after washing, unless several towels are used at once, because the large amount of moisture on the hands soon saturates a single towel. For removing blood from wounds, a paper towel is crumpled up into a sort of ball and then used as a sponge. Such balls absorb blood rapidly. The crude ornamental pictures, in color, on the towels, are of no advantage, nor are they, as far as is known, any objection.

herence of many to the theory that silver wire only should be employed for suturing purposes. Nothing could be more fallacious. Do we use silver hare-lip or acupressure pins? Why, then, employ silver sutures, when iron wire is stronger and far cheaper? When large and gaping wounds require the sutures to stand much tension, silver wire, if used, must be very thick. Iron wire of much smaller diameter, and therefore much more flexible, gives an equally strong suture, and in addition to being better adapted to the purpose is much cheaper. I recollect that, in hospital practice, nearly eight years ago, I discarded silver wire, which cost one dollar for each small coil, and bought, at a hardware store, enough iron wire for ten or fifteen cents, to last many months. The nicest iron wire I have seen, and which I now use for the purpose, because it is strong, very flexible, and free from elasticity, can be bought for five cents a spool. If it becomes a little rusty, it can be rubbed clean in a moment, should the operator object to the small amount of oxide of iron upon it."

NEW FACTS ABOUT DR. O. W. HOLMES.

THE following amusing instance of English insularism was handed us by a friend who chanced to consult a paper on Oliver Wendell Holmes, his Writings and Philosophy, by Robert F. Green, which occupies thirty-two pages of the thirty-fifth number of the Proceedings of the Literary and Philosophical Society of Liverpool for 1881. Among other "facts" about Dr. Holmes the writer gives these: "Besides the Professorship at Dartmoor, he founded and carried on a medical school at Tremont and had a large private practice."

It must be confessed that this is no more singular than the biography of Tennyson we recently saw in an Indiana newspaper headed by a cut of Longfellow.

THE BERLIN POLICLINIC.

THE Berlin Policlinic, 3 Fiegelstrasse, celebrated last November its first anniversary day. During this time more than two hundred medical men, amongst them many strangers, have attended it.

Specialties are taught in monthly courses which begin every first working day of the month and last every day during the whole month except Sunday and holidays.

To the Berlin Policlinic two laboratories, one for chemistry and one for histology, are attached. In both medical men find ample opportunity for executing researches on scientifical objects. The first of January a third laboratory, destined for working in Bacterioscopy, will be opened. At the same time a monthly course of Bacterioscopy will join the other courses.

RELATIVE COST AS LEGAL STANDARDS, OF UNITED STATES PHARMACOPŒIA AND DISPENSATORY.

IT is to be presumed that those who wish to have the United States Dispensatory, a commentary upon the Pharmacopœia, substituted for the Pharmacopœia itself as the legal standard for drugs in this State, at the least wish it to be always the latest edition of their favorite authority. As it is now the fifteenth edition of the Dispensatory which comments upon the sixth revision of the Pharmacopœia, if they wish to keep up with their standard they must buy a copy of that work twice and a half as often as they would of the Pharmacopœia, the present standard, and as the retail price of the Pharmacopœia is $4, while the Dispensatory is $8 — twice as much — it would cost them, even at the present rates, just five times as much to enjoy their desired uncertain standard. But as the publication of the Pharmacopœia began thirteen years before its commentary, the Dispensatory, and the price of the former edition of the Pharmacopœia was only about $1.50, while that of the Dispensatory has always been about as much as now, it would, with the former editions of these works, have cost really much more than this.

ELECTRIZATION OF THE SYMPATHETIC AND PNEUMOGASTRIC NERVES, WITH SIMULTANEOUS BILATERAL COMPRESSION OF THE CAROTIDS.

DR. J. LEONARD CORNING, of New York, writes in the *New York Medical Journal* (February 23d) advocating a method of electrization which he believes to possess a substantial value.

Advantage is taken of the fact that at a point situated between the angle of the lower jaw and the hyoid bone, on the one hand, and between the internal border of the sterno-cleido-mastoid muscle and the continuation of the tracheal line on the other, one may embrace by one electrode three important structures at once, namely: (1) the internal carotid; (2) the pneumogastric nerve; (3) the sympathetic nerve. Besides these important structures, we have the jugular veins, adjacent subsidiary nerve-stems, etc. Taking into account the physiological functions of the three principal structures named, it will be seen that galvanization exerts a threefold action on the encephalon, due to (1) diminution of the amount and pressure of the cortical blood-stream; (2) contraction of the cerebral capillaries; and (3) retardation of the heart's action (*when currents of considerable strength are employed*).

The apparatus consists essentially of a bifurcated conducting rod admitting of the application of an electrode on the two sides of the neck simultaneously, with provisions for adjusting accurately the current through each pole. Of course, precautions are laid down in view of the importance of the structures acted upon. The amount of compression of the vessels as well as the strength of the current must be carefully watched. Dizziness and syncope must never be allowed to be produced.

Therapeutically the author reports admirable results in congestive headaches, which may be cured in a few minutes. He also has hopes (the experience being not yet sufficiently extended to prove their success) of its value in epilepsy and incipient general paralysis. The galvanic current is generally preferable to the faradic.

Besides the more obvious physiological effects already referred to, the author notes the following phenomena in connection with the procedure described: (1.) Dilatation of the pupil. (2.) Drowsiness. (3.) Dizziness (where too great pressure or excessively strong currents are employed). (4.) Drooping of the eyelids. (5.) Retardation of the heart's action (where strong

currents are used. (6.) Pallor about the lips and upper portion of the face. (7.) Muscular weakness, as proved by the dynamometer; the subject, if standing, complains of weakness in the knees. (8.) If the compression and strength of the current be great, syncope may be produced. (9.) Diminution of the temperature over the parietal bones. Lombard's thermo-electric differential calorimeter shows a very considerable difference between the peripheral temperature and that of the head. (10.) Very interesting is the observation that the primary stage of excitement incident to etherization is cut short by resort to this method, and the amount of the anæsthetic required proportionately reduced.

Deaths reported 2641 (no reports from New Orleans, Buffalo, and Milwaukee): under five years of age, 694: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 434, consumption 425, lung diseases 406, diphtheria and croup 125, scarlet fever 98, diarrhœal diseases 54, typhoid fever 43, measles 20, whooping-cough 20, puerperal fever 19, erysipelas 18, cerebro-spinal meningitis 17, typhus fever six, small-pox three. From *typhoid fever*, Philadelphia 14, Chicago five, New York, Brooklyn, Baltimore, and Lawrence three each, Boston, Cincinnati, Pittsburg, and Holyoke two each, St. Louis, District of Columbia, Fall River, and Salem one each. From *measles*, New York eight, Baltimore six, Philadelphia and Brooklyn two each, District of Columbia and Pittsburg one each. From *whooping-cough*, New York four, Pittsburg three, Philadelphia, Boston, Baltimore, Cincinnati, and Fitchburg two each, Brooklyn, District of Columbia, and Cambridge one each. From *puerperal fever*, Chicago seven, St. Louis three, New York two, Philadelphia, Boston, Baltimore, Cincinnati, Nashville, Salem, and Northbridge one each. From *erysipelas* New York 10, Chicago three, Baltimore and St. Louis two each, Philadelphia one. From *cerebro-spinal meningitis*, New York six, Chicago, St. Louis, Lowell, Lawrence, Holyoke, Quincy, Woburn, Amherst, Holliston, Nantucket, and Natick one each. From *malarial fevers*, New York five, Brooklyn and St. Louis two each, Philadelphia and Baltimore one each. From *typhus fever*, New York and Brooklyn three each. From *small-pox*, Philadelphia two, Nashville one.

Five cases of small-pox were reported in St. Louis, Cincinnati one; scarlet fever 35, diphtheria 13, and typhoid fever 11 in Boston.

In 101 cities and towns of Massachusetts, with an estimated population of 1,428,666 (estimated population of the State 1,955,104), the total death-rate for the week was 18.21 against 17.07 and 20.31 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending March 8th, the death-rate was 22.5. Deaths reported 3773: acute diseases of the respiratory organs (London) 384, whooping-cough 138, measles 109, scarlet fever 94, fever 44, diphtheria 25, diarrhœa 25, small-pox (Sunderland seven, Birmingham four, Liverpool two, London and Wolverhampton one each) 15. The death-rates ranged from 13.8 in Birkenhead to 35.1 in Preston; Birmingham 19.6; Bradford 20.2; London 21.3; Leeds

21.7; Leicester 22; Sheffield 24.5; Liverpool 25.6; Nottingham 26.2; Blackburn 26.9; Sunderland 28.4; Manchester 29.3. In Edinburgh 20.3; Glasgow 27.5; Dublin 26.

For the week ending March 8th, in the Swiss towns, there were 49 deaths from consumption, lung diseases 22, diarrhœal diseases 25, diphtheria and croup 12, whooping-cough 12, typhoid fever five, erysipelas two, puerperal fever two. The death-rates were, at Geneva 35.7; Zurich 11.8; Basle 13.9; Berne 33.3.

The meteorological record for the week ending March 22d, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM MARCH 22, 1884, TO MARCH 28, 1884.

HAMMOND, JOHN F., colonel, and surgeon. Now in New York City, on sick leave of absence, will, after the expiration of his sick leave, await orders in that city. Paragraph 8, S. O. 70, A. G. O., March 26, 1884.

GIBSON, R. J., first lieutenant and assistant surgeon. Relieved from duty at Fort Hays, Kans., and ordered to Fort Wingate, N. M., for duty. Paragraph 3, S. O. 58, headquarters Department of the Missouri, March 18, 1884.

CROSBY, WILLIAM D., first lieutenant and assistant surgeon. Relieved from duty at Fort Huachuca, A. T., and ordered to Fort McDowell, A. T., for duty. Paragraph 1, S. O. 20, headquarters Department of Arizona, March 15, 1884.

EDIE, GUY L., first lieutenant and assistant surgeon. Assigned to duty at Fort McIntosh, Texas.

ROBERTSON, REUBEN L., first lieutenant and assistant surgeon. Assigned to duty at Fort Ringgold, Texas.

S. O. 33, paragraphs 3 and 4, headquarters Department of Texas, March 17, 1884.

GANDY, CHARLES M., first lieutenant and assistant surgeon. Assigned to duty at Fort Brady, Mich., as post surgeon. Paragraph 6, S. O. 56, headquarters Department of the East, March 22, 1884.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING MARCH 29, 1884.

GREEN, E. H., passed assistant surgeon, to the Greely relief steamer Thetis.

MARSTELLER, E. H., passed assistant surgeon, to the receiving ship Colorado, New York.

BRYAN, I. H., passed assistant surgeon, resigned, to take effect April 10, 1885, with leave of absence till that time, and permission to leave the United States.

RUSH, C. W., passed assistant surgeon, to the Naval Academy.

GYNÆCOLOGICAL SOCIETY OF BOSTON. — The next regular meeting of the Society — a quarterly meeting for informal discussion — will be held at the Medical Library Rooms, second Thursday of April, at four o'clock P. M. It is especially desired that all members should be present. Lunch served at this session.

HENRY M. FIELD, M. D., *Secretary.*

SUFFOLK DISTRICT MEDICAL SOCIETY. SPECIAL MEETING. — A special meeting of the Suffolk District Medical Society will be held at 19 Boylston Place on Wednesday, April 9th, at 7.45 o'clock, to appoint delegates to the meeting of the American Medical Association. By order of the President.

H. C. HAVEN, *Secretary.*

The *Section for Clinical Medicine, Pathology, and Hygiene* will meet at 19 Boylston Place, on Wednesday, April 9th, at eight o'clock. Dr. F. I. Knight will present a paper upon The Laryngeal Complications of Pulmonary Phthisis. Drs. S. W. Langmaid, E. W. Cushing, and F. H. Hooper will open the discussion. Dr. G. L. Walton will read a paper entitled Hysteria as affected by Removal of the Ovaries. Dr. John Homans will open the discussion.

ALBERT N. BLODGETT, M. D., *Secretary.*

Lectures.

THE OPERATION OF OVARIOTOMY.

A LECTURE DELIVERED BEFORE THE FOURTH CLASS STUDENTS IN THE HARVARD MEDICAL SCHOOL.

BY JOHN HOMANS, M. D.,

Surgeon to the Massachusetts General Hospital, and Clinical Instructor in Harvard University in the Diagnosis and Treatment of Ovarian Tumors.

In publishing the following lecture to students it may be proper for me to say that I have opened the abdomen for various purposes two hundred and three times. I have done the operation of ovariotomy one hundred and fifty-nine times. My first five cases of ovariotomy were performed without any antiseptic precautions whatever and all died. In the next one hundred cases I used antiseptic agencies, including spray. Of these thirteen died and eighty-seven recovered. Since then I have operated for ovariotomy fifty-four times with four deaths. My last thirty cases have all recovered. I ought, in this connection, to say that I have never declined to operate but once, the patient in that case having been already tapped to the amount of 2270 pounds in five years. I have operated upon all the other cases that have come to me, and although my late continued success is doubtless owing to good fortune, I feel that I can now perhaps do the operation better than I could at first.

THE OPERATION OF OVARIOTOMY.

Preparation of the Patient. Usually little preparation is required. For forty-eight hours before the operation I restrict the diet to flour gruel made by boiling equal parts of milk and water together for about an hour, gradually adding the flour until the gruel is made smooth and free from lumps. I order half an ounce of castor-oil about twenty hours before the operation, and an enema just before etherization. The object of these measures being to empty the bowels completely so that they will not interfere with the operation by their distention, nor by being plugged prevent the passage of flatus afterwards. If the patient has not taken a hot bath for some weeks, and if her strength will permit, I order one the day before operating.

The Anæsthetic. Ether is the best. It does not cause much vomiting if nothing is taken into the stomach for five or six hours before its inhalation.

Menstruation. I prefer not to operate while the menses are present, and seldom do so. The best time is about two days after the catamenia have ceased.

Exceptional Procedures. Sometimes it is necessary to tap the patient a week or two before ovariotomy to enable her to breathe more easily, to take more food, to lie down, to secrete more urine, or to lessen her weight and size that she may bear transportation. I have done it in exceptional cases for all these reasons. I drew by tapping sixty pounds of ovarian fluid from a woman in a tenement house out of town, brought her to the city in an ambulance,[1] and removed an ovarian tumor weighing fifty pounds. We could hardly have transported this woman with a tumor weighing one hundred and ten pounds. Again I have in six instances operated while a hæmorrhagic flow was going on from the uterus, because the catamenia had come on so irregularly that after waiting and postponing the operation it seemed that no calculation could be made. All these patients recovered.

Instruments required. A scalpel, a probe-pointed bistoury, a director, dissecting forceps, Nélaton's cyst forceps (at least six pairs), two Dawson's clamps, strong compressing forceps, with short and long blades for holding bleeding points, or bands of adhesions, of these about a dozen pairs, a large trocar with rubber tube attached for emptying the cyst, retractors, needles, a needle holder, carbolized silk and catgut, a steel sound, a catheter, Dieffenbach's hæmostatic forceps, Paquelin's thermo-cautery, and an aspirator (all the metallic instruments except the knives should be nickel-plated), three dozen towels, about forty clean soft sponges of various sizes, which have been soaking for several weeks in a five per cent. solution of carbolic acid. I have three barrels filled with solutions of carbolic acid, and these barrels are kept full of sponges. Each barrel is used alternately. Some of my sponges have been soaking for ten years. I formerly used sponges but once, but now I use them over and over after they have been cleaned; hot water bottles to put about the patient; several large clean tin pails, brandy, an enema syringe, plenty of hot water to wash the sponges if the operation should be bloody or protracted, several clean rubber aprons for myself and my assistants, that I may not soil my clothes, nor be thinking about it, a strap to buckle over the patient's knees and under the table, and wristlets to confine her hands.

Spray. I always use the spray and need a steam atomizer. I do not believe that the spray is absolutely essential, but I have had very good success with it, and have never known that it has done any harm.

There are other instruments that I carry with me, but those mentioned above I consider *necessary*, because although you will often need only a scalpel, a director, a pair of dissecting forceps, sponges, ligatures and sutures, yet you may need *all* your other instruments when you least expect to. *Never economize* when preparing for ovariotomy. Besides these things you will need the dressings for the wound, carbolized gauze and cotton-wadding, to fill up the void made by the removal of the tumor. You will also need a broad strip of sticking-plaster and a flannel binder to put around the patient over the dressings. I always wash my hands and forearms thoroughly with a nail-brush in carbolized water before beginning an operation and require my assistants to do the same.

Operating Table. A narrow operating table is necessary in order that your patient may be easily within reach from either side, eighteen or twenty inches being about the right width. In a private house I usually put two or more small tables or stands together, or lay a narrow ironing board from one table to another.

Etherization. The patient is not etherized in the operating room unless her respiration is very labored, in which case you may wish to shorten the period of etherization as much as possible. The dress having been tucked up, and the lower extremities covered with a blanket, the patient should be securely fastened to the table. For this purpose a broad strap is buckled around the table over the patient's knees, and her wrists are secured in soft padded leather wristlets connected by straps beneath the table. The abdomen is then uncovered and the carbolic acid spray (three per cent.) turned on. The abdomen is next wiped with a clean carbolized sponge, and two minute incisions, or marks,

[1] Loaned by Dr. Whittemore, Superintendent of the Massachusetts General Hospital.

are made about two and a half inches apart between the umbilicus and pubes in the linea alba, as a guide after the rubber sheet is in place. The spray is then shut off, and the skin of the abdomen dried with a clean towel. A rubber sheet about a yard and a quarter square, having a hole eight by four inches in the centre, through which the operation is performed, and the edges of which hole have been spread with adhesive plaster, is then applied to the abdomen, this sheet covering the patient to the neck and below the knees.

Positions and Duties of the Seven Assistants. I like to have seven, but I can get along with a less number. No. 1 etherizes. No. 2 stands opposite me on the patient's left hand, and helps to put compressing forceps on the bleeding points before the peritoneal cavity is opened. He then compresses the abdominal parietes, and after the cyst is removed ties vessels or keeps the intestines within the abdominal cavity if they tend to escape. No. 3 arranges and gives me the instruments. No. 4 stands on my right hand, sponges the wound, and catches any cyst-fluid that might run back into the abdomen. No. 5 stands on my left hand and draws up the peritonæum at the upper part of the wound, so that I may tap the cyst as high up towards the sternum as the incision will allow. He also gets the Paquelin's cautery ready when I am about to divide the pedicle. No. 6 supplies No. 4 with sponges, and me with towels, which he has kept clean and warm. In keeping the sponges ready for me he has much the most active duty among the assistants in a long and difficult operation. Finally, assistant No. 7 oversees the spray, and keeps a tally upon paper of the number of sponges placed in the abdomen and taken out. This duty is a responsible one. This plan is simpler than counting the sponges beforehand, as it sometimes happens that a sponge is torn in two, and as the important point is not to sew up a sponge within the abdomen I think it safer to count those that go in and come out rather than all the sponges before and after the operation scattered about the room.

Perfect silence should be kept by all the assistants and spectators.

The steps of the operation are these: (1.) Make the incision down to the rectus muscle. (2.) Stop all bleeding in the abdominal walls. (3.) Open the abdomen and explore for adhesions. (4.) Tap the cyst as high as possible. (5.) Detach the adhesions. (6.) Draw out the cyst and clamp the pedicle with Dawson's clamp, burn it off with the cautery, tie it, and remove the clamp. (7.) Examine the other ovary, and remove it if necessary. (8.) Thoroughly sponge out the abdominal cavity. (9.) Close the wound. (10.) Apply the dressings, and put the patient in bed.

(1.) The incision should be made in the median line rather nearer the pubes than the umbilicus, and at first less than three inches long, to be extended upwards if necessary, but always to the left, because the umbilical vein runs upwards to the liver on the right. This incision generally suffices, and one beyond five inches is rarely necessary. (2.) All bleeding must be stopped before the peritonæum is opened. I use compressing forceps, and prefer the little instruments called Dieffenbach's forceps. To each one I tie a piece of small fishing line about twenty inches long, and put a little weight of lead at the other end. When I see a bleeding point I pick it up with the little forceps and throw the weight and line over the patient's side. I attach this line in order that none of the forceps may fall into the abdomen if I knock them off. It is much easier to work through an opening surrounded by these little instruments than through one bristling with forceps, each one of which is five or six inches long. (3.) Explore with your hand or with a nickel-plated steel sound for adhesions, unless the cyst obviously slides down and up with the breathing of the patient. If the tumor is surrounded by ascitic fluid a certain amount runs out, and is conveyed by the rubber sheet into a pail on the floor. If there are adhesions to the walls you may separate them more or less before disturbing the cyst, although you must be careful not to rupture it. But adhesions to the omentum and intestines are better left till you have emptied the cyst by tapping. (4.) Tap the cyst with the large trocar, and be sure that the end of the rubber tube is in the tub under the table, or else the fluid will run over the floor. As the fluid escapes the cyst becomes flaccid, and can be drawn out. After some of the fluid has escaped I draw up the wall of the cyst on the trocar, and fasten it by the lateral toothed clamps, which hold it tightly. The canula thus fastened becomes an excellent handle, and with it the cyst is drawn out. If in tapping I happen to strike a small cavity and do not lessen the size of the tumor much, I seize the cyst wall with two or more of Nélaton's cyst forceps and hold it outside the wound while I withdraw the trocar and pass my hand into the tumor to break down the septa, if they are not too vascular and solid. If I think it unsafe to break down the interior of the cyst on account of probable hæmorrhage within the cyst, I withdraw my hand, wipe it carefully on a carbolized towel, and enlarge the incision. I now lift the tumor out of the abdomen, and secure the pedicle in Dawson's clamp. If there are serious and extensive adhesions to deal with, I sometimes secure and divide the pedicle. Then I have the tumor more movable, as it has been freed from its attachments to the uterus and broad ligament. I also know that no hæmorrhage can be going on within the cyst. All this time the assistant opposite me and the one on my right hand are carefully preventing any cyst fluid from running back into the abdomen. (5.) Separate the adhesions. While the tumor is being withdrawn, adhesions to the parietes, to the omentum, or intestines will show themselves. If they do not seem vascular they can be separated by the fingers. If vascular they may be divided by the cautery, or tied with catgut or silk in two places, and divided between the ligatures.

If a portion of the cyst wall is very adherent to the bowel it is best to cut out the adherent part and leave it. I then peel off its inner secreting surface if I can without doing violence. Great delicacy must be used in handling adhesions to the bowels or liver. I now examine the separated omentum for bleeding points, or leave it till the cyst has been removed and then do so. It is best examined by spreading it out on a warm carbolized towel. If bleeding vessels are found they must be tied, and the ligatures cut short. (6.) I clamp the pedicle with Dawson's clamp, because this squeezes the pedicle tighter than I can do it with a ligature, and then pass a small needle, threaded with a loop on which hangs a long silk ligature, through the pedicle close to the sulcus made by the compressing clamp, then I divide the loop and remove it. Next, after surrounding the pedicle and protecting the intestines by a warm carbolized towel, I burn through the pedicle with

Paquelin's cautery. I pass my ligature before dividing the pedicle, lest the latter should happen to slip out of the clamp and escape me while I am burning it off. After the pedicle is divided the tumor (which has been supported by an assistant that it may not drag on nor tear the pedicle) is removed, and the pedicle, still held in the clamp, is tied with Tait's knot, which I have described to you, and which you will find figured in his book. I now remove the clamp, and if there is no bleeding I cut the ligature close to the stump and let it drop back into the pelvis. I used to leave the ends of the ligature long until I was ready to close the abdomen, and then pull the stump up and cut them off, but one may possibly forget all about the ligatures, and leave several feet of silk unnecessarily within the abdomen, or the search for them may be tedious, as they may wind themselves around the folds of intestine and mesentery, and tear them when being withdrawn. The use of Dawson's clamp and the cautery are not absolutely necessary, but I feel safer when I use them. (7.) Examine the other ovary, and remove it if it contains cysts of the size of a filbert or is otherwise diseased. (8.) Thoroughly sponge out the abdominal cavity with sponges prepared as I have told you. I am particular in mopping up the spaces between the uterus and rectum and the uterus and bladder. I use soft sponges about two and a half inches in diameter, held in Nélaton's cyst forceps. When my sponges come out dry and clean I leave one in its holder behind the uterus, and do not remove it till I have passed all my stitches through the abdominal parietes, then if it comes out wet I resume my sponging before closing the incision. (9.) I put a soft, flat sponge over the bowels beneath the wound, and proceed to put in my sutures. These include the peritonæum and all the different layers of the parietes, and are best passed by having a needle at each end of the suture, and passing each from within outward with a needle holder. As the sutures are passed the opposite assistant ties the ends loosely together, and the assistant on the right hand wipes off any blood that may ooze from the needle holes externally, while the flat sponge within catches any that may run down from the holes made by the needles in the peritonæum. I now remove the little compressing forceps or "snappers," as I call them, and generally find no bleeding going on. I withdraw my sponge from Douglas's space, take out the flat sponge, and tie the sutures. Then I put in any superficial sutures that seem necessary. I use carbolized silk of various sizes, but for the deep sutures through the abdominal walls I use small needles and as large silk as will pass through the eyes. (10.) Apply the dressings, and put the patient in bed. I put on dry carbolized gauze and enough new and clean cotton-wadding to fill up the hole left by the removal of the tumor. Next I pass a broad piece of adhesive plaster tightly round the abdomen over the dressings; this should be wide enough to extend from just above the trochanters to the sternum. Over this I pin a soft flannel swathe. The patient is then carried to her bed on the operating board, and gently slid off the board into the bed. If there has been any shock hot water bottles are placed around the patient, care being exercised that they shall not burn her.

Treatment after Ovariotomy. The patient should be left alone with her nurse, and should be allowed to sleep as long as she will. Sometimes there is vomiting, and sometimes not, but nothing need be done for it. As a general rule the temperature is not much affected; it rarely rises above 100° F. during the whole convalescence. An opiate is generally required during the first twelve hours after the operation, and sometimes never again. I generally give one sixth grain of morphia or its equivalent in solution by means of Bigelow's opiate enema syringe, which holds a drachm of fluid, and was figured in the Boston Medical and Surgical Journal, vol. xcvi. (1877), p. 360. The cardinal principle in taking care of a patient after ovariotomy is to give all opiates and stimulants *by the rectum* until flatus passes the bowels or until all symptoms of nausea or vomiting have been absent for many hours.

Original Articles.

CASES OF RUPTURE OF THE LIVER.[1]

BY F. W. DRAPER, M. D.

The following notes are offered in illustration of the gravest form of injury to which the liver is subject, as the result of external violence: —

I. The patient in this case was a boy, Robert S., four years old, amiable in disposition, and sound in health. He lived with his mother and step-father, the latter being the janitor of an apartment hotel, in the basement of which the family of three occupied rooms.

The incidents of the boy's last hours of life can be presented best in their chronological order. Between three and four o'clock in the afternoon of a day early in November he was playing with two of his mates of his own age. The three lads had found, in a vacant lot, a low tank or pan, made of quarter-inch boiler-iron, an appliance which masons had used for drying sand. It measured five feet in length, two feet in width, and its sides were eight inches high at the highest. In one end of it was a collection of cobble-stones and brickbats, occupying less than half the space. The iron had become warped by use, and this, with some irregularities in the surface of the ground on which it rested, made it possible for the boys to tilt or rock the pan a little, as they would a boat. In the course of their play the children fell from their improvised boat, striking on the soft ground. Robert in his turn fell out; one of his mates said that he seemed to be hurt a little and that he cried, but that he presently resumed his play and seemed none the worse for his slight mishap.

At a quarter past four he was seen "playing horse" with one of his fellows, running about in the square in front of his home as if he were entirely well.

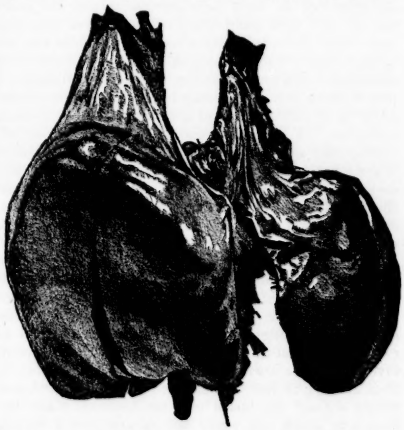
At five o'clock a lady saw him playing "hop-skip" with her little boy, and both the children were as active as usual.

He was next seen crossing the square going towards his home, a distance of about two hundred feet from the spot where he was playing last. A young girl of his acquaintance spoke to him here, and he replied, to use her own words, "in a sort of way as if he was sick;" although he was not crying, nor did he tell her, in answer to her question, that anything had happened to him. This little girl, evidently truthful and having no motive to be otherwise, was the only one of all who saw him who noticed anything unusual about him.

[1] Read before the Boston Society for Medical Improvement, March 24, 1884.

The statement of the step-father, D., is in order at this point in the narrative. He said that at five o'clock, as he was standing at the front door of the hotel looking out upon the street, he saw Robert run across the square as fast and as smart as he ever saw him run; then he saw him pass down along the side of the building toward the rear entrance to the basement where he lived. In about seven minutes he (the step-father) went down stairs to the basement and found the boy kneeling in front of a squirrel cage which was on the cemented floor; his head was resting against the wires of the cage front. He complained that he was sick, that his "belly ached." D. took the boy into an adjacent room and began to undress him; in the course of this proceeding the lad's head dropped forward and his body swayed. Upon being asked how he got hurt, the child replied feebly, "Velocipede!" and spoke the name of a neighbor's boy, one of the two with whom he had been playing during the afternoon. D., who up to this time had been alone with the boy, now called his wife, Robert's mother, from an upper room in the hotel where she was at work. Presently the child had a convulsion. When he had recovered from this and was raised from the lounge on which he was lying, he screamed with pain. To his step-father's further questions as to the manner of his injury, his only reply was that he was sick.

Between half-past five and six o'clock a lady occupying rooms immediately over the basement went down stairs to the janitor's rooms to get a key which he had promised her. She knocked at his door, and after some delay, during which she heard a whispered conference between him and his wife, she was admitted. Entering she saw the child lying on the lounge in great distress, turning from side to side, pale, moaning, and apparently dying. She besought the man to go out for a physician. He went with reluctance, and soon returned with word that his search was unsuccessful. The boy had another convulsion, and the women urged D. to go again for medical aid. He responded to their appeals after some delay, and reappeared presently with a physician, whose relation to the case proved brief and simple. The child was moribund on his arrival, and death occurred in about ten minutes, at twenty-five minutes past six o'clock. The doctor's examination of the patient, before death and immediately after, led him to conclude that fatal internal hæmorrhage had taken place; while certain marks upon the body not present, according to the mother, when the child was dressed in the morning, aroused his suspicion still further, and suggested to him the propriety of summoning a medical examiner, upon the supposition that the boy had died by some form of violence. It was thus that the case came to the writer's notice for investigation.



An autopsy was made eighteen hours after the death. The surface of the body was strikingly pale; the lips were fully blanched, and there was scarcely any post-mortem staining of the dependent parts. There were recent ecchymoses of small size on the forehead, the right cheek, the chin, the inner side of the right knee, just above the crest of the ilium, the back of the right hand, and the back of the right thigh. Besides these, there was a faint red discoloration, of the size of a silver dime, two inches below the left nipple and a little to the left of the middle line. This was the only mark on the skin of the chest and abdomen.

An ecchymosis, or line of ecchymoses, three eighths of an inch wide, extended obliquely across the back of the left hand. Upon the front of the left thigh were two parallel, dusky blue marks, corresponding in oblique course, in width and in color with that on the hand. These parallel linear ecchymoses were two inches apart. On the front of the right thigh and in direction continuous with the upper one of the two just mentioned was a narrow discoloration apparently made at the same time and by the same means as these. In other words, by placing the left hand with its palm posterior and its thumb against the outer side of the extended left thigh, one could readily believe that the ecchymoses upon the back of this hand and upon the front of the two thighs were to be associated in the matter of their cause.

In the peritoneal cavity there was a pint of liquid blood; a single, small, imperfectly formed clot lay against the under surface of the liver. The heart was pale but without other abnormality. The lungs were anæmic. The right lung at its posterior inferior border showed three small extravasations extending to the depth of half an inch. At the lower part of the posterior mediastinum, especially on the right side of the vertebral column, the tissues were infiltrated with effused blood.

The spleen and kidneys were exsanguine. The stomach and intestines were normal, and contained the partially digested remains of the last meal. The peritonæum behind the stomach displayed a ragged rent through which two fingers passed easily. The subperitoneal connective tissue behind the liver and duodenum, and overlying the right kidney, was extensively infiltrated with blood, and there was a similar alteration in the appearance of the parts in the left inguinal region and over the left side of the bladder behind and above the symphysis pubis.

The liver was ruptured through its entire thickness, the right lobe being freely opened from its anterior edge, just to the right of the gall-bladder, in a direction

almost exactly at right angles to the transverse plane of the body, and to such a depth that only about a finger's breadth of hepatic and peritoneal tissue remained at the posterior surface of the organ as a bond of union. The surfaces of this principal rent were

ragged, granular, pale, and slightly blood-stained. This extensive lesion was revealed plainly when the abdominal cavity was first opened.

Besides this extensive fracture other secondary injuries appeared on the surface of the liver. The lobus quadratus was ruptured superficially, presenting a fissure three quarters of an inch deep and an inch long. On the upper surface of the organ, to the right of the chief rupture, there was a linear and superficial rent about two and a half inches long, in general direction parallel with the principal opening, and in depth extending scarcely beneath the capsule. The outer edge of the right lobe showed limited areas of extravasation beneath the surface. Section of these revealed many deeply-seated, irregular rents in the substance of the organ. There was marked anæmia of the viscus, but in other regards there was nothing abnormal in its structure. The gall-bladder was torn from its attachments, and retained its connection only by its right border and by its duct.

Examination of the head discovered a small but distinct and recent ecchymosis under the scalp, just above the occipital protuberance. The skull was uninjured. The brain, instead of being anæmic as were the other organs and tissues, was moderately injected.

The manner in which this child received his fatal injuries has never been satisfactorily established. Diligent investigation by skillful detectives failed to solve the mystery. An inquest was held which resulted in a judicial report rehearsing the few facts determined in evidence, and indicating probabilities with sufficient clearness. It declared that "the death of Robert S. was caused by a rupture of the liver and consequent shock and hæmorrhage, which rupture of the liver was caused by a heavy pressure or violent blows upon the body of said Robert S. by some person or persons. There was evidence before the court of inquest tending to show that the step-father of said Robert S. had at various times abused and severely and unreasonably punished said Robert by blows and otherwise, and also that the said step-father was alone with said Robert just before said Robert died, and while so alone with the said Robert he, the said step-father, had time and could have inflicted the fatal wound upon the liver, and also other severe and fresh wounds, internal and external, that were found upon the body of said Robert S."

The step-father, D., was indicted for manslaughter, but has never been tried, the evidence being deemed insufficient to warrant a presentation of the case to a jury.

In the absence, then, of positive knowledge of the manner of the death, we are allowed to indulge in speculation upon the limited data in our possession. These data permit three hypotheses only: —

The first supposition is that the boy was thrown down and injured by means of a velocipede. But this is based on the step-father's statement that the child told him so, and on this alone. It is quickly disposed of by the fact that the velocipede alluded to was within doors during the entire afternoon.

The second theory is the one which, at the judicial examination of the accused, was strongly hinted at as that upon which he would base his defense, and it had the support of a well-known medical expert, who stated in private his belief in its value for that purpose. This view associates the fatal lesion of the liver with the slight fall from the iron pan on the hill-side more than three hours before the boy's death. It assumes that there is no irreconcilable incongruity in the following chain of circumstances: that a boy of four years, weighing fifty pounds or less, should fall on his left side over a thin, upright barrier eight inches high; that he should thus produce the double marks on the left thigh, and at the same time rupture the right lobe of the healthy liver not only nearly through its entire thickness antero-posteriorly, but in various other directions; that after this, though crying a little at the first after his hurt, he should go on with his play as if nothing had happened, and within an hour, regardless of the hæmorrhage then inevitably progressing in his abdomen, and undisturbed by the serious injuries to organs on both sides of his diaphragm, should run and jump after his usual manner; that at the end of all his sport returning to his home, without any accident on the way, he should "run as fast and smart as ever," to use his step-father's words; that seven minutes later he should be found faint, weak, and sick, unable to walk or stand; that upon this, the first intimation of serious trouble, the usual train of symptoms of fatal internal hæmorrhage should rapidly supervene; and that in a little more than an hour after the onset of grave indications, preceded by nearly two hours of apparently complete immunity from any sign of disability consequent on the injury, death should terminate the case.

A third view may be formulated thus: A child to whom, during the year since his mother's second marriage, his step-father has shown great dislike, manifested in repeated and cruel punishment for trivial or fancied offenses, returns to his home after an afternoon of play with his customary companions. No accident has happened to him to interrupt, except for a moment, his active exercise. The step-father, who has found recent occasion to reprimand the boy for staying out too late in the afternoon, sees him running home, and determines to administer still further discipline. Going presently to the basement where the child is alone, the mother being engaged in a distant room, the man proceeds to execute his purpose in his usual harsh and impetuous manner. The boy struggles. Two blows with a rod or similar instrument leave their marks on his thighs and left hand. For the purpose of restraining him in his attempts to free himself, or in order to subdue him by measures more persuasive than flagellation, or, perhaps, by accident only, the man brings his knee with force against the right hypochondrium and right infra-mammary region of the boy while he lies on his back on the floor. Observing that a startling change in the child has followed this act of violence its author desists, but before calling the mother to the scene he invents what he believes to be a reasonable explanation of the emergency, and puts into the injured lad's mouth words about his playmate's velocipede which he never uttered.

This theory of the case, though mainly evolved from the imagination, has in its favor its entire consistency with the undisputed facts.

II. Mary M., a married woman, aged twenty-eight, was found lying dead upon the floor of her bedroom at three o'clock in the afternoon of a Sunday in December, 1883. Two hours previously she had been speaking, at her own door, to one of her neighbors, nothing in her face, clothing, or demeanor betokening any departure from her usual condition of health. At this time her little boy, five years old, was the only one in the house with her, but during the morning her

husband had been at home, and had been heard engaged in a quarrel with her about domestic matters, and addressing her in words more emphatic than elegant or tender. Both husband and wife were noisy, especially when, as was not unusual with them, they were intoxicated.

What occurred between one o'clock, when one of the woman's neighbors saw her in her usual health, and three o'clock, when another neighbor found her dead upon the floor, is not known definitely, but the child, when he opened the door to admit the latter caller, said that his father had given his mother "a dirty licking." The husband was not in the house, but on his return, two hours later, he said to the officer who arrested him that while out for a walk he had been told that his wife was dead; that before he went out he had struck her, but with his open hand only; that in so doing he knocked her down, and she vomited afterward. Further details of the affair are not available.

Very little was discovered upon the body or about its surroundings at the preliminary inspection to aid in determining the manner of the woman's death. She was lying on one side at full length in the middle of the floor. Her face showed a fresh ecchymosis of both lids of the right eye, a contusion of the cheek, of the upper lip, and of the chin, with dried and clotted blood in the nostrils and about the mouth. There were also bruises on the left arm, over the left hip, on the left shin, and on the right hand.

Of some consequence in connection with the lesions found upon dissection were two very faint, scarcely visible, discolorations on the abdomen; one of these, an inch in diameter, was an inch and a half above the navel (just where the waistband of the dress-skirt passed around the body), and a little to the right of the median line; the other was immediately beneath the left border of the ribs in the mammary line. These were the only marks visible on the thoracic and abdominal walls.

The autopsy was made nineteen hours after the discovery of the body. The surface of the cadaver was pale, and the mucous membrane of the lips and mouth was notably exsanguine. There was a very slight degree of cadaveric staining of the dependent parts.

In the peritoneal cavity were forty-five and a half fluid ounces of liquid blood. This large effusion had proceeded from an extensive rupture of the liver which, beginning at the notch in the anterior edge, passed backward, involving the entire thickness of the organ nearly to the posterior surface, leaving as a hinge at the back a band of hepatic tissue and peritonæum less than an inch thick. The rent followed the direction of the broad ligament, and its surfaces were irregular, granular, and slightly reddened by blood.

Other fissures, superficial in situation and character, appeared at the base of the lobus quadratus and on the lobus spigelii adjacent to the main fracture. On the upper surface of the right lobe, near the anterior margin, and about two inches distant from the deep rupture, there was a superficial bruise of the liver two and a half inches in diameter. The liver was anæmic, but otherwise was of healthy appearance; it weighed three and a half pounds. The gall-bladder was uninjured.

The other organs of the body presented nothing abnormal beyond the pallor due to anæmia.

As in the previous case, so in this, accurate information concerning the manner of the death is wanting; but it is probable that in the course of the "dirty licking" which this amiable husband thought it to be his duty to bestow upon his wife his knee or foot came down with masculine force upon the parietes overlying the liver and split that organ from front to back.

A brief mention of some of the questions naturally suggested by cases like the foregoing will form a fitting conclusion to this paper. Allusion will be made in this connection to injuries of the severer kind only, to deep fractures of the liver, and not to superficial lacerations of the organ, from which, to borrow the words of Mr. Pollock, "the patient may recover without much suffering and without any particularly marked indication of the existence of the injury."[1]

And, first, it may be asked, what kind and what degree of force are required to produce the severe injuries described? Casper says,[2] "Healthy organs never rupture spontaneously, . . . and even healthy organs are never ruptured but by the employment of considerable violence. Therefore, rupture of the liver, lungs, etc., may uniformly be taken as conclusive evidence of the previous application of great violence." That this statement, by high authority, expresses the rule, is scarcely open to doubt. Although the liver is, of all the abdominal viscera, the most frequently ruptured, its large size, exposed situation, and friable structure counting against its immunity, yet if the organ be not softened or enlarged by structural changes, if it be of normal size and sheltered in its proper position with the overhanging grating of ribs in front and at the side, and with the vertebral column and thick spinal group of muscles behind, it would seem to be well favored by nature to escape casualty, and Casper's allusion to "great violence" does not appear to be too strong. The recorded cases of serious rupture of the liver are generally illustrations of the severer forms of accident. The victim has jumped or fallen from a height of many feet, striking on a pavement or other unyielding surface; or the wheels of a loaded wagon have passed over his body; or a heavy object has fallen upon him; or he has been caught between the buffers of cars; or he has received a blow from a windlass bar; or he has been thrown with great force by machinery against a wall; or he has been kicked by a horse; or a locomotive has struck him; or in the course of an altercation he has fallen under his assailant, who thereupon, half rising, has pressed his knee with great vigor into the right side of his prostrate antagonist, — these are the usual stories of the manner in which the injury was received. But are there no exceptions? Must one, as Casper states it, "uniformly" predicate great violence upon deep ruptures? We are concerned rather to establish whether such lesions do not sometimes follow comparatively slight accidents or a moderate exhibition of force. Diligent search may be rewarded by the discovery of a very few exceptions to prove the rule, but can hardly bring to light enough to show more than a rare chance that deep lacerations of the liver may follow trivial falls or blows.

Well-authenticated cases of spontaneous rupture must be reckoned among the curiosities of surgical literature. Beck[3] alludes, in a foot-note, to such a case "which proved suddenly fatal during labor," but qualifies the value of the report somewhat by the

[1] Holmes's System of Surgery, iii., page 896.
[2] Handbook of Forensic Medicine, i., page 132.
[3] Elements of Medical Jurisprudence, ii., page 377.

statement that the patient had probably been "injured by violence on the part several months previous."

Taylor states[1] that the liver "may be ruptured merely by a sudden action of the abdominal muscles; an accident of this kind happened to a person who was endeavoring to avoid a fall from his horse."

The symptoms of a deep rupture of the liver are commonly those of collapse. There is coldness of the entire surface of the body, with marked pallor; the features are pinched, anxious, and exsanguine. The pulse is feeble, the respiration is sighing. There is extreme restlessness, though the mind remains clear. The sense of faintness and distress is prominent. The abdomen is distended and tympanitic. There is pain, referred chiefly to the injured region. Some of these symptoms are due directly to the violent solution of continuity in the parts involved, to the stretching and tearing of the peritonæum, and, in less measure, to the laceration of the liver itself. But most of the striking indications of profound collapse arise from the inevitable hæmorrhage, which is rapid and profuse, according to the depth and situation of the lesion and the size of the hepatic vessels which are rent asunder. It is easy to understand that any considerable laceration of this large organ must result in serious loss of blood, for its three distinct sets of vessels endow it with special vascularity, while the conditions under which the blood escapes are such as to promote rather than to restrain the effusion. The natural aids to spontaneous hæmostasis in external wounds are absent; the exposure to the air and to cold, the retraction of the divided vessels within their sheath, and their compression by the contraction of the tissues around them, — all these are wanting. "A laceration of the liver is in much the same condition as an external wound with a warm sponge upon it; the flow of blood is favored by the high temperature of the interior of the body. And the hepatic veins, not being contractile or surrounded by any loose tissue, cannot close or even collapse."[2]

Under such circumstances, favoring profuse and rapid bleeding, immediate and profound shock would be the natural and usual consequence of the grave injuries under discussion. But this is not a rule without exception. Cases have been recorded in which extreme damage to the liver has been borne with extraordinary immunity from bad symptoms. Dr. Fergus has reported such an instance.[3] A boy of seventeen fell from the shaft of a cart, the wheel of which passed over the abdomen just below the false ribs. The boy complained of pain in the abdomen, but not of a severe character, and not materially increased by pressure; the amount of shock was trifling. "He seemed to suffer very little." The case ended fatally, however, and the autopsy revealed a deep laceration of the liver and a rupture of the gall-bladder. In another case, mentioned by Taylor,[4] a man applied at a hospital for treatment for an injury to his abdomen, but as there were no urgent symptoms present to confirm his story he was sent away. A few hours afterward he was found dead. On inspection the liver was discovered to be lacerated nearly through its diameter, and a basinful of blood was in the abdominal cavity.

A question of considerable medico-legal interest is involved in these cases, and is naturally suggested by this statement of the usual symptoms. To what degree does a deep rupture of the liver disable the patient and render him incapable of exertion or of resistance if injured by an antagonist in an affray? The first answer that occurs is that such an injury would immediately and fully overcome its victim, and that a man would be so prostrated by the sudden shock as to be unable to make further effort save with great pain and difficulty. Many reported cases, indeed, afford ground for such an answer, if precedents were required. In a case within the writer's personal knowledge, in which a young and muscular man threw an elderly opponent upon his back on the ground, and there knelt upon him with great force, rupturing the liver externally and breaking up its substance to a considerable extent internally, the immediate effect upon the pugnacity of the older of the two wrestlers was very marked; he was fully deprived of his power to resist, and had to be carried home. In another instance a policeman was endeavoring to take a prisoner to the station-house; the latter attempted to escape, and the officer knocked him down and fell upon him, his abdomen receiving a blow from the officer's knee. The prisoner suffered great pain when he was lifted up, but he was able to walk to the station with assistance; he soon became insensible, and died in twenty minutes. The liver was found ruptured in three places, and upwards of three pints of blood were effused in the abdomen.

In very rare cases, indeed, the consequences are less serious. The injury may be borne with such comparative freedom from shock, and the hæmorrhage may be so slow in its progress, that the patient can walk without assistance and perform other acts that seem extraordinary. But the books do not record any instance in which a child has continued at his active play with evident enjoyment after receiving injuries to the liver like those described in Case I. Taylor formulates the rule clearly; "although," he writes,[5] "in cases of severe wounds we may allow that persons may perform various acts of volition and locomotion, yet the presence of a mortal wound, especially when of a nature to be accompanied by great loss of blood, must prevent all *struggling* or violent exertion on the part of the wounded person; such exertion we must consider to be quite incompatible with his condition."

With regard to the gravity of these injuries to the liver as affecting the life of the patient there can be but little difference of opinion. Most surgeons would agree with Hennen that a deep wound of this organ is as fatal as if the heart itself was engaged.[6] But it would be an error to insist that all cases, even of the severer type, terminate as speedily as the two reported at the beginning of this paper. While it is true that in nearly all the instances of deep rupture of the liver death quickly removes the sufferer, the interval after the injury being longer or shorter, varying from a few minutes to thirty-six hours, according to the amount of hæmorrhage, in some notable exceptions life is prolonged for several days. In these unusual cases the fatal issue is due commonly to peritonitis, the patient's system having had time to react from the primary shock and to develop secondary inflammation of the torn peritonæum. A case is related,[7] however, in which, the liver having been ruptured through its entire thickness by a fall from a third-story window, the

patient survived ten days, and died at the end of that interval by hæmorrhage. In the case reported by Fergus, already referred to, where the primary symptoms were insignificant, peritonitis developed on the second day; on the fourth day the patient was pronounced convalescent, but on the sixth day he was suddenly seized with severe pain, and a second onset of peritonitis declared itself. Death ensued on the ninth day, and at the autopsy the liver was found ruptured quite through its substance to the depth of two and a half inches from its anterior border. The gall-bladder also was broken.

Not only may death be delayed in these cases, but also, under peculiarly fortunate conditions, considerable progress toward the repair of the injured tissues may be made. A man was admitted into Guy's Hospital in a state of collapse, exsanguine, and complaining of intense pain in the abdomen. The pain gradually subsided, and the patient appeared to be doing well, when he died quite suddenly, three days after the accident, while attempting to raise himself in bed. The peritoneal cavity contained a large quantity of blood. There was an extensive fracture of the liver. The torn parts were well adapted to each other, and pretty firmly united by the fibrine of the extravasated blood.[1] In another case, under treatment at St. George's Hospital, a man had fallen, striking on his back, fracturing the seventh cervical vertebra and injuring the spinal cord. Death occurred three weeks after the accident. "An extensive rupture was found on the upper surface of the right lobe of the liver. This rupture, which measured five inches in length, was perfectly united with the exception of some few points where the peritoneal coat still remained broken. The rupture did not extend very deeply into the organ."[2]

These indications of what nature may do in the direction of mending a badly injured tissue serve to show on the part of the liver an extraordinary indifference to violent treatment, and to confirm what has already been suggested, that the hæmorrhage is the main factor in the fatal result. In fact one of the lessons taught by the records of injury to this organ is its patient tolerance of abuse. Not only does it bear with resignation the standing and libelous reproach of incontinently getting "out of order," and rendering its unhappy owner "bilious," but it suffers more violent treatment without serious rebellion. Three cases may illustrate this.[3] By the accidental discharge of a pistol a man drove a ramrod through the abdominal wall into his liver, and laceration of that organ to a depth not ascertained was felt through the external wound. He had an abscess at the spot, but was discharged well in forty-three days. A boy, seven years old, was shot in the right hypochondrium, and a part of the anterior wall of the abdomen was carried away. The liver protruded through the opening. The patient had no proper attention for four days; at that time the exposed part of the organ was gangrenous. The sloughing portion, equal in amount to half of the right lobe, was cut away, and the boy recovered. A Hindoo, between sixty and seventy years old, was wounded with a spear. The liver escaped injury, but pushed through the abdominal wound. The extruded part, weighing an ounce and a quarter, was excised. The patient was well in three weeks.

[1] Holmes's System of Surgery, i., page 897.
[2] Ibid, page 897.
[3] From Eve's Surgical Cases, pages 319 and 320.

But although the liver will endure an astonishing amount of violence of the kind described, where much hæmorrhage is not the result, and, as Harley has pointed out,[4] may tolerate, "with complete immunity from danger, repeated puncturing by exploring needles and trocars," its deep rupture, attended inevitably with hæmorrhage, is, as we have seen, a far more serious matter, and usually gives early opportunity to study its post-mortem appearances.

The external evidences of the cause of death are generally summarized in the pallor and marked anæmia of the surface of the body betokening the effusion of blood within the abdomen. If one looks for large and deeply discolored ecchymoses upon the thorax and abdomen to correspond with the extensive lesions beneath he will commonly be disappointed in his search. Such outward proof of violence is rarely observed. One of the earliest lessons which the examiner in medico-legal cases learns is that there may be the most wholesale destruction of thoracic and abdominal viscera without any external sign of the force which produced it. Of this the cases under our present study are illustrations.

The interest of the internal examination attaches chiefly to the appearances presented by the injured liver. The rent, if it be deep, will generally be found in the large right lobe or at the boundary line between the two lobes, following the direction of the broad ligament above and of the longitudinal fissure below. There is good reason for this latter location; the notch in the anterior edge, indicating the partition between the two lobes, is sufficiently deep and exposed to make it a good point of departure for any force acting like a wedge, while the corresponding gap at the posterior border rests upon the unyielding vertebral column, and is thus afforded a support which favors the forcible separation of the two lobes from the front backward. If there are other secondary, superficial fissures they are seen mostly on the convex surface, near the front, and in general direction parallel with the main fracture; rarely they take a transverse or very oblique course. The edges of the lacerations are irregular in outline, and are but slightly parted. The torn surfaces of the organ present a rough, granular appearance, moderately stained with blood, with some partly detached masses of hepatic substance hanging loosely upon them. The blood which has escaped from the broken vessels is found collected in the deeper parts of the abdomen and pelvis rather than in close relation to the liver, and is singularly free from coagula.

REASONS FOR THE EARLY REMOVAL OF OVARIAN TUMORS.

BY J. C. IRISH, M. D., LOWELL.

WHILE the discussion of this subject may present very little that will not have already been carefully considered by ovariotomists, still it may be of interest to those members of the profession who are occasionally confronted with this very grave question: to decide for their patient when in its progress an ovarian tumor should be removed. Some, too, may be led to consider whether the quite prevalent opinion that a patient should not be exposed to the dangers of ovariotomy before her health is enfeebled or her life imperiled may not be erroneous and unfortunate.

In reference to the time when ovariotomy should be advised, Professor Peaslee, in his Treatise upon Ovarian Tumors and Ovariotomy, laid down the following rule: "When the general health has become somewhat impaired, and not till then, the time for ovariotomy has arrived."

This precept of Dr. Peaslee, given in 1872, has since been, in the main, accepted by American writers upon ovariotomy. Drs. Thomas and Emmet, however, in their late publications, give this rule with much less emphasis than did Dr. Peaslee, and with some very important exceptions.

While this teaching has produced a very general impression among the profession at large that ovariotomy should not be undertaken until the patient's heaith is considerably deteriorated, yet among ovariotomists at the present time a different sentiment is fast gaining ground, many of them advising the operation while the patient is still in robust health. The wisdom of this course of action is already apparent in the rapidly increasing per cent. of success.

Spencer Wells in the edition of his work published in 1872 gave essentially the same rule in regard to the best time for ovariotomy as that just quoted from Dr. Peaslee. But in 1882 he says: "I have become more and more disposed to advise the removal of an ovarian tumor as soon as its nature and connections can be clearly ascertained and it is beginning in any way mentally or physically to do harm." Yet a glance at the last hundred cases in Mr. Wells's published table would persuade the reader that he really in practice followed the first clause of his rule rather than the second, for among this hundred there appear seventeen cases in which the tumor weighed ten pounds or less, one of them weighing only four pounds. Now it is very improbable that ovarian tumors of this size could be doing any appreciable harm, either mental or physical. It is more probable, rather, that they were removed as soon as their character could be clearly ascertained.

One great argument in favor of delay is, that after the tumor has become sufficiently large to distend and press for a time upon the peritonæum, it so changes the character of that membrane as to render it less liable to a severe grade of inflammation, and that the patient, therefore, is in less danger of death from peritonitis.

Referring again to Mr. Wells's last hundred reported ovariotomies, we find that not one of the hundred died of peritonitis, though there were eleven deaths, and in seventeen cases the weight of the tumor was only ten pounds or less.

In his series of one hundred cases from January 1, 1869, to January, 1871, there were ten deaths from peritonitis. The average weight of the tumors in these fatal cases of peritoneal inflammation was twenty-two and one third pounds, while the average weight in the whole series was twenty-one and one third pounds.

Of about forty cases of ovariotomy that have come under my observation, but two died of peritonitis, and in both instances the tumors were large and had exerted considerable pressure upon the peritonæum.

So far as these histories teach anything, they show that the size of the tumor is not an important factor in determining a fatal result from peritonitis. They also indicate the recent rapid decrease in the frequency of this formidable sequel to ovariotomy, the series of fourteen years ago embracing ten deaths from this cause, while the later contains not one.

The experience of other ovariotomists in this regard, as I learn by inquiry and from their written statistics, coincides with that of Mr. Wells.

Peritonitis, therefore, has well nigh ceased to be a prominent cause of death after ovariotomy, although the operation as a rule is performed much earlier than ten years ago. There are several causes, I think, that have contributed to this favorable result. Important among them is the improved method of treating the pedicle, namely, by short ligatures and replacement within the abdominal cavity, a mode of treatment that has very generally been substituted for the clamp and long ligatures brought out at the lower angle of the wound. Another is the great care now exercised in preventing the entrance of any extraneous matter into the abdominal cavity, or if this has been unavoidable, its thorough removal, together with the great pains taken to render the condition of the peritonæum an aseptic one.

Another reason given for deferring the operation until the patient is debilitated by the disease is that thus a certain amount of comfortable life is secured to her which would have been lost in the event of a fatal issue. At a time when about one third of the whole number who submitted to the operation died this argument was a cogent one. But now, when not one in ten, excluding the delayed and tapped cases, die, and when, in the near future, not one in twenty will die from the operation, this plea for delay loses its great force.

The dangers, too, that constantly increase and always menace a patient with an ovarian cystoma, are so great as to far outweigh all the advantage that any postponement of the operation can bring.

Although adhesions of the cyst wall to surrounding structures may form at any time during the growth of an ovarian tumor, yet in the majority of cases they do not occur before the cyst has become large enough to entirely fill the abdominal cavity, and are most common in those cases where the tumor has reached an age of two or more years. They are, therefore, complications that an early operation would generally avoid. While adhesions, however extensive they may be or however closely they may attach the cyst to the abdominal parietes, omentum, intestines, or brim of the pelvis, are not a contra-indication to ovariotomy, still they convert an operation that in itself is really a very simple one to one of great difficulty and hazard. I have seen three cases in which an attempted ovariotomy could not be completed on account of immediate adhesions to important viscera. In two of the three the disease had existed about three years, without much impairment of health, and without giving very great inconvenience. For this reason, in accordance with the rule we are discussing, they were advised to defer an operation until some more urgent necessity for it arose. The consequence was that they each, for three years, carried about with them an ugly, mortifying deformity, and then died of an affection of which they might have been cured three years before.

In passing from this well-worn topic of adhesions to the discussion of degenerative changes that take place, the following case is presented as an illustration of the former, and especially as an example of the insidious general poisoning that may follow degenerations of even the interior structure of an ovarian cystoma: —

Miss C. N., Rockville, Conn., aged nineteen; operation September 19, 1879. The tumor was noticed one year before. Her general health had apparently been

unimpaired until three months ago, when she began to lose flesh and strength. Latterly her failure in health had been rapid.

September 18th we found her with a pulse 110, a rapid respiration, and a hectic flush upon each cheek. No abnormality of the patient's lungs could be found, and her attending physician, Dr. Kisley, as well as myself, was at a loss to account for her condition of hectic. All was explained, however, when the contents of the tumor were withdrawn. The liquid had the physical appearance of pus of considerable consistency, and in amount was about nine quarts. The tumor had evidently been a multilocular cyst whose division walls had become degenerated and broken down. Hence the blood-poisoning that would undoubtedly have ended the patient's life very soon had not removal been effected. The cyst was adherent to the parietal walls anteriorly and at each side. The pelvic and intestinal adhesions were also extensive. Many of them were firm fibrous bands, with blood-vessels of considerable size, while in several places the cyst was agglutinated to the intestinal surface. The separation of these adhesions was attended with many difficulties and occupied two and one half hours. The patient finally recovered after a very tedious convalescence, and is now in good health.

Tracing the natural history of an ovarian tumor through its entire course, it will be found to have caused death in one of two ways: either by its size interfering with the normal functions of the abdominal and thoracic organs or by degenerative changes that have occurred in its structure. But cases of the former class are rare, and especially so, because the great size is usually relieved by tapping when the tumor becomes oppressively large. Such a tumor that would have become fatal at last on account of its size alone now becomes so, if it has been tapped, by reason of degenerative change. Practically, therefore, an ovarian cystoma, subjected to no surgical interference except tapping, produces death by structural degeneration of its tissues.

These parasitic growths, as Mr. Wells terms them, differ in their histological character from the normal tissues in which they take their origin, and the deviation becomes more and more marked as their development progresses. Like most other adventitious growths, their vitality is feeble and their tenure of life, as a rule, is short.

In any given case we cannot predict when this process of degeneration will begin, and oftentimes when it has advanced very far towards the decay and death of some tissue of the cystoma it gives no sign by which it can be recognized, and we then have a dead tissue in the living body, diffusing a subtle and deadly poison through the whole organism. In many instances the progress of this septicæmia towards a fatal result is rapid, in others slow, as in the case just described.

Again, our first warning of cystic degeneration may come from some accident; a not uncommon one being rupture of the cyst walls, and the escape of its contents into the abdominal cavity, producing a very fatal form of peritonitis.

The following case is an illustration of an accident more rare than cyst rupture, and due to degenerative change affecting the pedicle: —

Mrs. S., Lowell, age forty-five; operation June 19, 1881. She had always been in good health until October, 1880, when after a cessation of the menses for three months she noticed an enlargement of the abdomen. The patient regarded herself as pregnant, in which opinion she was confirmed by medical advice until June 12th, when a careful examination revealed unmistakably the presence of an ovarian tumor. It was at this time that the operation should have been performed, yet as her general health was seemingly unimpaired, the removal of the tumor was delayed. Two days after Mrs. S. had a severe attack of pain localized in the right lumbar region.

The pain speedily subsided, but similar attacks followed at intervals of a day or two, and when they occurred the patient became pale and the extremities cold. Meanwhile the tumor very sensibly increased in size, and at the same time the patient's strength rapidly failed. The tumor was removed one week from the time of the first examination. When the cyst was tapped with a "Wells' trocar," a large quantity of clotted blood passed through the tube. Very soon when the withdrawal of liquid had removed all tension from the cyst walls, and as I was drawing the sac out through the incision, there appeared a stream of fresh blood through the tube. The clamp was at once applied to the pedicle and further hæmorrhage stopped. Its application required only a few seconds, still a large quantity of blood must have been lost.

The cause of the attacks of pain and the accompanying pallor, with coldness of the hands and feet, was now apparent. The internal portion of the pedicle had become broken down by degenerative changes, and one or more of the large blood-vessels had been opened, thus pouring blood into the sac from time to time as much as the distensibility of its walls would allow. It was from this cause that the tumor had increased so rapidly in size and the final great hæmorrhage, added to those preceding, had so exsanguinated the patient as to prove fatal just as the operation was being completed.

In June, 1881, at the request of her attending physician, I saw Mrs. ——, of Milford, Mass. She had an ovarian cystoma of recent development that extended two or three inches above the umbilicus, but not distending markedly the abdominal walls. Her general health had, seemingly, been unaffected by the growth of the tumor. Therefore, in deference to the generally accepted rule of practice that ovariotomy should not be resorted to while the patient is in vigorous health, the removal of the tumor was deferred. Some three months after the sac ruptured, and Mrs. —— died in seventy-two hours of peritonitis.

All the perils of ruptured cysts, bleeding pedicles, and septicæmias from broken-down and dying tissues of the tumor can be averted by an early operation.

And does not the avoidance of all these dangers far exceed in the welfare of the patient every possible advantage, if there be any, that can come to her by delay? In short, is not an early interference, while the tumor is both small and recent, the wisest and most prudent course?

Mr. Lawson Tait, in his work upon Diseases of the Ovaries,[1] presents a very strong argument in favor of the early removal of ovarian tumors, based upon their pathological character and manifest malignant tendency. After describing the great variety of epithelial cells found in cyst cavities, their mode of development, and their varied departures from the normal epithelial cell, he concludes that most ovarian tumors have, at least, an element of malignancy, and that their prompt

[1] Page 144 et seq.

removal is urgently demanded as a protection against the systemic infection of the patient with cancer.

These conclusions of Mr. Tait are corroborated by the after-history of Mr. Wells's one thousand cases. A large proportion of the whole number were living at the time of the report, yet of those who had died thirty-three had died of cancer, and if a complete history of all these cases could have been obtained this number would probably have been largely augmented. The fact that so many patients at one time in their life develop an ovarian tumor, at another cancer, or, as quite often occurs, a uterine fibroma, seems to indicate that these growths are simply different manifestations of one and the same abnormality of the general system.

In this connection the case of Mrs. J., of Connecticut, from whom an ovarian tumor was removed June 12, 1879, is interesting. Age forty-five. No children. When she reached the age of thirty-nine her menstrual periods gradually became more frequent and the flow more profuse, until for the past six months there has been an almost continuous sanguineous discharge from the vagina. Last July, that is, eleven months before the operation, she noticed a tumor in the right iliac region, which was painless, but had steadily enlarged. June 5th I made the first examination. Her general health was not greatly impaired, and that mainly by the menorrhagia and metrorrhagia of the past year or two. The tumor of the ovary did not greatly distend the abdominal walls. Fluctuation was distinct over the upper portion, and its boundaries could be distinctly traced. In the supra-pubic region a hard ovoid body could be felt, which was the fibroid uterus, uniformly enlarged to about six times its normal size. The ovarian tumor was of the dermoid variety, weighed about fifteen pounds, and was free from adhesions. The patient made a rapid recovery. The menorrhagia ceased, and the fibroid afterwards did not increase in size.

Mrs. J. remained in good health for about two years, but subsequently died of cancer of the uterus. So in this case we had the simultaneous existence of an ovarian tumor and a uterine fibroma, and subsequently a cancer.

Summarizing my own experience, there have been eight cases in which I operated before the general health had been visibly impaired, and when the tumors had not reached an advanced stage of development. Of these all but one recovered, and the death of the that one was due to an accident. This patient's general condition had not apparently been affected. A small cystoma, without adhesions or other complications, was removed. After the operation she complained very bitterly of a terrible prickling sensation throughout the abdominal cavity, which could hardly be controlled by large doses of morphine. Ten hours later bloody serum, the blood tinge being slight, began to exude in large quantities from the wound. This continued for about twenty-four hours. She died of exhaustion on the third day. I am certain that, by some mistake, a solution of carbolic acid many times too strong was used in sponging the abdominal cavity. The severe prickling sensation was characteristic of carbolic irritation. Also the pouring out of a large amount of serum would indicate that the peritonæum had been exposed to an irritant of some kind, and this probably was the carbolic acid. Certainly nothing in the previous condition of the patient, or in the operation itself, could account for the speedily fatal result.

Of the other cases I will give briefly the history of one, one entirely devoid of interest, except as illustrating the usual absence of any difficulties in the way of ovariotomy when the operation is performed early; and also as an example of the safe and rapid recovery that, with few exceptions, follows when an ovarian cystoma has been removed at an early stage of its growth: —

January 24, 1883. Mrs. H., White River, Vt., age twenty-four. Two children. After the birth of the youngest, two years ago, noticed a small tumor in the left iliac region, which had grown slowly but steadily, until it now extended several inches above the umbilicus. Before coming to me she had consulted several surgeons, who had told her that she had an ovarian tumor, but advised against an operation at that time because her general health was not affected, and because she was not suffering any great inconvenience. A few days later I saw the patient, and urged an immediate operation, because the tumor was not large, and was probably non-adherent, and because her general health had not been harmed by it.

She consented, and I removed an oligocystic tumor weighing about fifteen pounds. There were no adhesions, and the operation was attended with no difficulty. I wish especially to call attention to some of the unfavorable circumstances surrounding this case.

She came from her home in the country to the city, and occupied a small room in a crowded tenement house. Added to this was considerable mental disturbance lest she had been unwise in consenting to an operation, contrary to the medical advice she had received. Great anxiety, also, on account of her straitened circumstances contributed to produce a mental depression very unfavorable for ovariotomy. In a word, both her surroundings and her mental condition were as unfortunate as could well be conceived, but her physical condition for the operation was perfect. Without enumerating the tedious details of temperature and pulse from day to day, it is sufficient to say that the highest temperature reached was 101° F. upon the fourth day, and that this steadily declined, and became normal upon the tenth day, at which time she had practically recovered from the operation.

The ovariotomist, unfortunately, cannot elect his own time for the operation in a majority of cases, for many of them do not come under his care before the disease has reached an advanced stage, and before complications have occurred from adhesions, degenerative changes, or septic infection of the system, so grave as to render ovariotomy formidable and often unsuccessful. I have presented these reasons for early removal, however, believing, as I do, that ovariotomy will take a long stride in advance of its former success when it shall become the general and settled rule of practice to remove ovarian tumors as soon as their diagnosis can be clearly determined.

— A table prepared by the New Jersey State Board of Health shows the rate of mortality to be 16.32 per 1000 persons at Plainfield, and 26.98 at the town of Union. The population of the latter place, however, is only 5094. These are the extremes of sixteen towns. The death-rate for Jersey City, with 120,732 inhabitants, is given at 24.27, and for Newark, with 136,508 inhabitants, at 23.52.

Reports of Societies.

PROCEEDINGS OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M. D., SECRETARY.

MARCH 24, 1884. The President, DR. CHARLES D. HOMANS, in the chair.

ROUND-CELLED SARCOMA OF THE MEATUS AUDITORIUS.

DR. J. ORNE GREEN exhibited a photograph from a patient twenty-three years old with the following history: There had been otorrhœa since scarlet fever six years before, and when first seen by Dr. Green the meatus was filled with a growth like a polypus, fungous granulations covered the seat of an abscess which had burst over the mastoid, which as well as the petrous bone proved to be carious, and the patient was weak. After four or five days of supporting treatment there were a chill and fever. In consequence, he was etherized, an incision made into the bone, freeing grumous pus, and a drainage tube inserted, the growth being also removed. The septic symptoms now disappeared, but the progress of the growth was rapid, nodules appearing below and in front of the ear. Later, brain symptoms developed with œdema of the eyelid and cheek, and lastly coma that existed for three weeks previous to death, which occurred six months after first coming under observation. No autopsy was allowed, but the piece removed at the beginning was examined by Dr. Gannett and found to be round-celled sarcoma.

PECULIAR CASE OF VALVULAR DISEASE OF THE HEART.

DR. W. P. BOLLES presented the specimen, the history of which had been one of valvular disease with enlargement, dyspnœa, jaundice, and death. The cardiac sounds were those of mitral insufficiency, a loud and distinct murmur accompanying the systole, while there was no direct murmur. On autopsy, however, there was found to be not only insufficiency, but also a high degree of stenosis, only the tip of the finger being admitted. A large old ante-mortem clot was worn smooth toward the centre of the auricle, and was adherent at all other places. Remains of emboli existed in the lungs and a suppurating cavity in the right lung corresponded with a history of pneumonia ten weeks before. It was interesting that the patient had never had rheumatism, and that while there were no cardiac symptoms until within one or two years, yet that she had been told, thirty years ago, by the late Dr. Reynolds, Sr., that she had a very bad heart.

DR. F. C. SHATTUCK remarked that this case is an illustration of the fact recognized by all recent writers on heart disease, that valvular disease — and especially mitral stenosis — may be unattended by murmur. The presystolic murmur, when present, is very characteristic, but it is not infrequently absent and sometimes comes and goes. In the advanced stages of cardiac failure the auricular contractions are often so feeble that they cannot throw the valve into vibrations sufficiently forcible to give rise to any audible murmur.

DR. H. I. BOWDITCH thought that such histories should make us chary of needlessly giving a diagnosis and thus causing useless alarm.

DR. FRANCIS MINOT remarked that possibly the knowledge may have prolonged her life.

DR. O. W. DOE showed a

COLLECTION OF THREE GALL-STONES

passed by a lady, fifty-five years of age, at intervals of a week. The smallest measured one and two tenths centimetres in its broadest diameter; the largest, one and four tenths. Each attack lasted about two hours, the pain being chiefly referred to the right hypochondriac region, and was followed by jaundice, which disappeared in from two to three days. The patient had been leading an unusually sedentary life for two years past.

The treatment was by ether, morphia subcutaneously, and hot applications to the epigastric and hypochondriac regions.

DR. CHARLES W. WILLIAMS reported a

CASE OF FOREIGN BODY IN ORBIT.

T. W., seven years old, while playing with some boys was hit over the left eye with a stick. There was a cut through the skin about one quarter of an inch long; it was a little to the inner side of the eye, and a quarter of an inch below the eyebrow. The nurse reported that it bled freely, but nothing more than water dressings were applied, as it was supposed to be only a black eye. When seen, five days after the accident, the eye was closed, the upper lid swelled even with the eyebrow. The cut in the skin was still open, and discharging a small amount of pus. A probe could be passed backward about half an inch, but no foreign body could be detected with certainty. There was neither redness nor extravasation of blood under the ocular or palpebral conjunctiva, and the vision was nearly normal, $\frac{8}{10}$, and corresponded with that in the other eye. Poultices were applied for two days. On a second examination with a probe a suspicion of grittiness was detected. The child was etherized, and first some small splinters of wood, then a roundish piece, about half an inch long by quarter of an inch thick, was removed from the bottom of a pocket, extending about half an inch directly backward from the cut to a point between the orbital roof and the sclera, and just to the inner side of the superior rectus muscle. On questioning the boys more carefully it seemed that the stick which hit the eye had been used as a trellis for plants, and the sharp end which was buried in the ground had penetrated the lid. This partly decayed wood, absorbing the blood and moisture from the orbital tissue, had become so soft that a probe failed to detect its presence with certainty until it grated against a bit of sand which was attached to the wood. After the removal of the wood the wound was poulticed for two days; the discharge had then ceased, and the swelling of the lid was nearly gone; vision as before, $\frac{8}{10}$. At no time did the child complain of any pain in or about the eye. He ate and slept well, and enjoyed his play.

DR. H. L. BURRELL showed a

TUMOR OF THE UTERUS.

The patient was fifty-nine years old, and had not menstruated for twelve years. Four years after the cessation a small lump appeared in the right inguinal region. In a year there were three or four smart uterine hæmorrhages. There was dyspnœa, probably from bronchitis, but no pain. Dr. Burrell had made an exploratory incision after death to see if an operation would have been feasible, and found that it must have been very difficult. A cyst on the right side was bound to the right iliac vessels. Both the round ligaments were very tense, and held the uterus fixed as if bound to the rectum or spine. There proved to be no

such adhesions. An examination with the probe two months ago had given the uterus an apparent depth of two inches. This was accounted for by the obliteration of the internal os, beyond which was a cavity four inches deep. The cervix was obliterated, and it was hard to say where the vagina ended and the uterus began, thus increasing the danger of wounding the ureters had removal taken place during life. There was no peritonitis, the cause of death being bronchitis.

Dr. Minot inquired if it is not rare for uterine fibroids to develop after cessation of the catamenia.

Dr. C. D. Homans mentioned some cases of large fibroids that stopped growing before that time.

Dr. R. H. Fitz said that the uterine fibroid commonly becomes calcified in advanced life.

AMPUTATION IN SENILE GANGRENE.

Dr. J. C. Warren presented a specimen. A short time ago Mr. Jonathan Hutchinson had read a paper before the Medico-Chirurgical Society advocating amputation above the *expected* line of demarkation in cases of senile gangrene of the toe, that is, he would amputate above the knee-joint, that being about where the disease would probably stop if let alone. Other papers have been called out by this of Mr. Hutchinson's. Dr. Warren's patient had the typical foot and the senile appearance, but claimed to be only fifty-one years old, and there was an indefinite history of injury. Dr. Warren had amputated at the point of election two days ago, and there is as yet no return of the disease. The skin was good to the malleoli, and the skin flap was taken from a convenient height. The anterior tibial artery was found to be plugged, but the posterior tibial was sound. The results of waiting have been so poor that it is interesting to see what success will follow a change of treatment.

Dr. Gannett asked Dr. Warren whether there had been any injury to the foot previous to the appearance of the gangrene, and further called attention to the fact that the condition of the vessels was favorable to the development of gangrene, provided an inflammatory process were set up by any injury or other cause.

Dr. Warren said that there was a vague history of inflammation, of freezing, and of being stepped on by a horse.

Dr. F. W. Draper then read the regular paper on

RUPTURE OF THE LIVER.[1]

Dr. Fitz said that two possibilities, in addition to those suggested by the reader, occurred to him in explanation of the origin of the ruptured liver in the case first reported. On the one hand it was conceivable that the child had been crushed between the tilting tank and the ground, supposing there was sufficient space between the two for the admission of the body; on the other, that his playmates had fallen upon him while stretched across the edge of the tank.

Either of these alternatives might account for certain of the external wounds as well as the internal injuries. Even if the first were impossible in consequence of the relation of the tank to the ground the latter was still tenable, and could hardly be refuted, even if denied by the children. The youth of the witnesses would, of necessity, materially qualify their evidence on this point.

The main argument against this theory, based upon the length of time and occupation of the boy in the interval between the play and the occurrence of serious symptoms would be controlled by the history of a case reported before this Society by the late Dr. J. B. S. Jackson, and recorded by him in his Catalogue of the Cabinet of the Society somewhat as follows: —

A girl, between four and five years of age, was run over by a baker's cart on Monday morning. Though feeling faint during the forenoon, and kept upon the bed, she was down stairs in the afternoon, on the floor with her playthings. On Tuesday she was out doors, in front of the house, and on the following day she went to the Common, at some distance from her home, and played about and rolled upon the grass. While returning distress at the stomach was complained of, which continued through the night, and was at times urgent; nausea and vomiting with cold perspiration were also present. On Thursday she was much relieved, but was confined to her bed, where she remained till her death, on Saturday, four days after the accident. The prominent symptoms during the last two days were frequent faint turns and progressive loss of strength.

A rupture of the liver was found extending nearly through the substance of the right lobe, and causing the separation of a mass equal to two inches and a half in diameter or more. The peritonæum was separated from almost the whole anterior surface of the right lobe by a thick layer of clotted and liquid blood. The peritoneal cavity contained about half a pint of blood, and blood was found in the pleural cavity with some ecchymosis.

Dr. Draper said that there was not enough space for the child to have been crushed between the tank and the ground.

CHRONIC RETENTION OF URINE.

Dr. Bowditch reported the case, which he had sent to an expert, from whom he had received a letter which was of interest. The patient had been getting up at night two or three times for two or three years. Several specimens of his urine contained from one and a half to two inches of pus in a six-ounce glass. This was two months ago, while now he can go to bed at eight and stay there until morning, and the urine is clear when passed, although it becomes cloudy at the bottom of the glass on standing. From the history it was evident that the bladder had not been perfectly emptied for two or three years. It rose above the pubes, and could be felt by the finger in the rectum. As the patient lived out of town he came into the city to a hotel, and there was astonished by the surgeon passing a catheter immediately after micturition and getting over two pints more urine without emptying the bladder. Aside from the use of the catheter the treatment has been dilute hydrochloric acid as a tonic.

Dr. Samuel Cabot said that surgeons not uncommonly have ample evidence that a bladder has not been emptied for years.

SUFFOLK DISTRICT MEDICAL SOCIETY.[2]

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.

ALBERT N. BLODGETT, M. D., SECRETARY.

THE MILK SUPPLY OF LARGE CITIES — *concluded.*

The leading principle with too many of the men engaged in the sale of milk in the city is to get trade, by any means possible, and build up a route to sell out.

[1] See page 339 of this number of the Journal.

[2] Concluded from page 325.

Such dealers have no pride in learning thoroughly the proper way to carry on the business; they do not care much what they sell or whether or not they make a legitimate profit if in the end they can sell out and come out even or a little ahead. The class of men who have the better portion of the trade, who have had experience in business, and money with which to carry it on, who want to sell a good article and make a fair profit, and who, if there were no ruinous competition, would not, from principle, take advantage of their customers, but would give every attention to their wants, only asking a fair return, are constantly harassed and annoyed and, as they term it, robbed by these so-called "pick ups."

Another trouble is found in the competition from stores. At the present price, forty cents per can at the car, a milkman pays 4.71 cents per quart for his milk. It is conceded that a milk-wagon cannot be run for less than two cents per quart by all having any knowledge at all of the business, and many close observers say two and one half. If we take the lowest figure the milk costs 6.71 cents at the consumer's door, or 7.21 cents if we take the higher. It is easy to imagine the feelings with which he would regard a card in a window, "pure milk, four cents per quart," when he may have one or more customers in the same block from whom he must get seven, and, if possible, eight cents per quart or not pay his bills.

That it would be an advantage to the business if the Board of Health would drive all storekeepers out of the business who are not willing to sell pure milk and sustain the price is clear. Whether the poor people who buy would be benefited by the advance in quality more than they would feel the advance in price is not so clear. At all events it is a fact beyond dispute that any man may, by a little inquiry, find out the character of the man from whom he proposes to buy, and need fear being cheated no more than he would in buying any other class of goods.

In reply to a question the same gentleman stated that the effect of feeding cows on ensilage was to produce a peculiar sweetish taste in the milk, which is not at all agreeable, and is also contained in the butter made from such milk.

In regard to the statement that a certain milk-producer is putting up milk at his farm in glass jars for delivery in Boston, the facts are as follows: I know the gentleman, and know the source of his milk. It is transported to Boston by rail, and always comes in ordinary tin milk cans. If he delivers it in Boston in glass jars it is put into jars after it reaches the city. It comes to Boston like all the rest of the milk.

DR. J. AYER asked the speaker, "Ought the citizens of Boston to receive milk as good as the farmers produce it, thirty miles in the country; or does the carriage, by cars or otherwise, injure its properties?' to which the reply was given that there is no reason why the milk when delivered at the door of the consumer should not be in every way equally as good as when it left the farm on which it was produced. The main source from which damage might be apprehended would be from too early collection before the temperature of the milk had been sufficiently lowered by cooling in water, or too high a temperature in transit in summer, or freezing in winter. These accidents are obviated by the cans being surrounded by ice as soon as they are placed in the car, or otherwise kept at the right temperature, which should, if possible, be maintained at 50° F.

Dr. Ayer also asked, "Is the milk injured by churning, or motion, in transportation? My impression has been that the carriage and disturbance were injurious."

The gentleman replied that the printed rules of the Milk Association, posted in the barn or on the premises of the farmer, requires every milk can to be full up to the stopper, so as to prevent all churning. It is also required that the cow's bag shall be washed or brushed before milking. The milk should be cooled in another building from that in which the milking is done, and should be kept in the stable no longer than absolutely necessary after being drawn from the cow. The cars used for the transportation of milk are placed on regular passenger trucks and ride as easy as passenger cars. The motion of the car does not affect the milk at all. The wagons used for delivering the milk after it arrives in Boston are made for that especial purpose, and are set on two springs, and have a peculiar rolling motion which does not shake the milk. With all the care which can be exercised the milk is injured far more in being carried about for distribution in the milk wagons after it arrives in Boston than in being carried thirty or even forty miles by rail. Even if delivered in the best possible condition, careless treatment after it is in the consumer's house will spoil it in half an hour. Often it is placed where the temperature is raised to 60° F. or 70° F., when it at once sours, and the consumer blames the milkman.

DR. BARNES asked if it is possible to preserve milk in good condition for seventy-two hours; to which it was replied that this is perfectly possible. A certain lot of milk was on one occasion missent, and for nearly a week was lost. When recovered the milk was in perfectly good condition in every way. The firm which the speaker represents, not milk contractors but milk dealers, supplies the line of steamships plying between Boston and Norfolk, VA. These steamers always take milk here for the round trip, as no supply can be depended upon in Norfolk. On their arrival in Boston after the trip to Norfolk the milk which is left over is always found fresh and sweet.

DR. BUCKINGHAM stated that the quality of milk is often materially affected by circumstances entirely independent of the age of the milk or its transportation. As a matter of fact the inside of milk cans is sometimes foul, and the corks sour. One way of preventing this would be the use of glass, as proposed by Dr. Morris. By this system, however, one would get the milk of only one cow in a glass, which would be objectionable. The expense of this course, which might be important, is a matter of which he knew nothing.

Condensed milk having been brought into the discussion, he thought that the Swiss condensed milk, the only one of which he has knowledge, contains a great deal too much sugar to be a fit food for babies or invalids.

In answer to a question about the opinion of the Society as to the value of one cow's milk for babies, Dr. Buckingham said that the theory in giving one cow's milk is to avoid variation in the quality of the food. Milk from one cow does, however, vary somewhat from day to day, and it is probable that the mixture of the milk of several cows will vary less than that of any one of them. This he knew to be the opinion of several members of the Society. It is also the view that is gaining ground in Germany.

DR. HARLOW asked how many of the farmers prob-

ably adulterate milk to any extent or in any way before sending it to the city.

In reply it was stated that such a thing was very rarely done. Probably not over two per cent. of the farmers attempt to tamper with milk in any way. It would be fatal to their interests to do so, as the milk from such dairies would not be accepted by the contractor nor allowed to go out. The principal adulterators are a set of dealers who supply milk for a minimum price, and in this way build up a large trade in order to sell out. A well established milk route has a considerable commercial value. Unscrupulous men often build up a business in this way, and then sell the route to other parties.

DR. E. T. EASTMAN stated that housekeepers often accuse the milkman unjustly. In a case known to him the servant was in the habit of taking off a portion from the top of the can, and supplying the deficiency with water, and the housekeeper complained that the milkman was delivering adulterated milk. This source of deterioration in the milk supplied to families is often forgotten, and the milkman is charged with adulteration.

In reply to the question how the supply of *cream* is obtained which is sold for table use at an advanced price, it was stated that the surplus of each day's milk was passed through a machine called the "separator," which removes the cream and leaves a pure skimmed milk which is sold to bakers, to families for domestic use, and for feeding to pigs. Another method of obtaining cream is also regularly followed. Each day cans of milk fresh from the dairy are poured into large receivers which are surrounded with ice, and are left undisturbed for twenty-two hours. At the end of this time it is skimmed with a conical skimmer, and about ten per cent. of cream obtained, which is the average amount of good milk.

DR. EDES asked how the milkmen are sure of the quality of milk which they supply to their customers.

The reply was made that the quality of the milk is examined each day, and sometimes a favorite dairy will be found unfit for use, and will be rejected, and a supply from some other source obtained in its place. Suspicion was recently aroused in respect to a dairy, and on "setting" the milk it was found to yield only six per cent. of cream. The milk from a neighboring dairy was also "set," and yielded fifteen per cent. of cream. Consumers would hardly have been satisfied if this milk had been delivered to them in glass jars sealed in the country, though they could not then accuse the milkman of tampering with it. Often the milk from a reliable dairy will be found sour, and, of course, must be rejected, and used for butter. The quality of the milk also depends on the food of the cow. Brewers' grains are not considered an unhealthy nutriment for cows, but the milk is thin and white.

In reply to a question by Dr. White as to how many cows are represented in one can of milk, it was stated that rarely would one can contain the milk of more than two cows. The farmer milks the cows in succession, and as soon as each cow is milked the milk is strained into the cans, which are successively filled and at once placed in water to cool. After arriving in the city the milk is mixed, and is then drawn into the service cans for distribution.

DR. BUNDY said that he had witnessed the operation of "mixing," and had seen water added in considerable quantities previous to filling the service cans for families.

DR. DAVENPORT asked if the milkmen consider the required standard too high? The reply was made that the milkmen in general know nothing about the standard, and but little about milk regulations or milk laws, but studiously endeavor to avoid the penalties.

The statement has been made that the cream sold by milkmen was obtained from creameries, as it was impossible to obtain good cream from the tops of their cans. Mr. Abbott stated that in his earlier experience as a milkman he found no difficulty in getting a large share of the cream, the motion of the cars was so slight and the sudden cooling with ice caused the cream to rise so that most of the cans have a heavy cream on them when reaching the city. Those that did not could be iced and kept over, as nearly every milkman carries a surplus.

Dr. Barnes stated that the Milk Inspector, in speaking of the arduous duties of his office, said that if the city would furnish him with a team, he could accomplish much more. Mr. Abbott produced the Milk Inspector's report for the year ending March 21, 1883, showing that the number of visits made and samples inspected was 1153, or, allowing three hundred working days, would be less than four per day, which Mr. Abbott thought, with our system of horse cars and good sidewalks, would not be a very laborious work for an able-bodied man. Our Milk Inspector receives $1800 per year, and has a clerk at $500, making $2300; divide this by 1153 and it will be seen that it costs the city of Boston nearly two dollars apiece for every sample of milk inspected. To this must be added $140 for analysis in fourteen cases, as a result of which thirteen persons were prosecuted and twelve convicted. In looking further we find that at that date eight hundred and sixty storekeepers or retail dealers have been licensed; is it possible that only that number of storekeepers in Boston have heard that there is a milk law! Such being the case, it is not to be wondered that the milk dealers speak with contempt of the Milk Inspector and his office.

DR. MARCY remarked that we should not forget that in the plan for furnishing milk as described and practiced by Dr. Morris all chances of contamination of the milk from dirty vessels, all manipulation by middlemen, and all abstraction by servants after the milk has been delivered, is prevented. The most of the objections urged against milk as now supplied would at once be removed. There seems to be no good reason why a plan which can be carried on in Philadelphia to the satisfaction of the consumer and at a fair profit to the projector might not work equally well in Boston.

DR. BLODGETT remarked that a part of the responsibility for adulterated milk undoubtedly rests upon the people consuming it. Very few people in the city know how pure milk looks, and expect a rich yellow milk at all times of the year and under all circumstances. Cows' milk is not all yellow, nor is it always yellow. The farmers endeavor to secure cows which will yield large amounts of milk, but the color is often very pale. The farmer gets three and a quarter cents a quart for milk, and he tries to get the largest possible amount from the cows. A farmer cannot furnish Jersey milk for three and a quarter cents per quart. If people demand a quality in milk which does not belong to it there are no doubt many milkmen who are willing to furnish it of any desired color; and thus the consumer unconsciously encourages adulteration.

Dr. Blodgett further stated that he had made some attempts to ascertain the methods employed in the handling of milk, and that he had seen and heard much which was new and interesting to him, and was particularly struck by the courtesy and freedom with which he had invariably been allowed to make any investigations or pursue any inquiries he thought desirable. He thought that the members of the Section would be favorably impressed with the care and scrupulous attention to cleanliness which are observed in all the operations to which milk is subjected in transit and until it is delivered to the milkmen for distribution. Of course all this does not in any way prevent these persons from adulterating it before they deliver it. But there seems to be no systematic adulteration, as we have too often been led to suppose. A visit to the large milk depots is calculated to inspire a greater degree of confidence in the quality of the milk supply than exists at present in the minds of the majority of consumers.

DR. BOWDITCH presented the following resolution:

Resolved, That the chairman be requested to appoint a committee of five, whose duty shall be to report upon the whole subject of the providing of milk for Boston, and suggest the means for obtaining it pure for the citizens.

The resolution was unanimously passed, and in accordance with its requirements the following committee was appointed: Dr. H. O. Marcy, chairman, Dr. A. N. Blodgett, Dr. E. W. Cushing, Dr. H. J. Barnes, Mr. L. F. Abbott.

On motion of Dr. Blodgett the thanks of the Section were tendered to the members of the Milk Producers Association for the important information which they have placed at the disposal of the Section in regard to the source, treatment, and adulterations of the milk supplied to the citizens of Boston.

THE SPAYING OF COWS.[1]

The second paper of the evening was entitled The Milk Supply of Boston, and the Benefit to be Derived from the Spaying of Cows, by MR. LLOYD F. ABBOTT, a former milk producer and dealer.

The paper was read by DR. G. E. MECUEN, who described the process as follows: —

As regards the spaying of cows there is little danger if properly done, and the mortality should not exceed one per cent.

Operation. An incision is made in the flank of the cow, left side preferred, as being handier for the operator, about four inches long, through the skin, then the muscles and fascia are cut, and the peritonæum divided, using the finger as a director. The hand is then introduced and carried upwards and backwards until the uterus is reached, when, by following the horn outwards, we find the ovary, and remove it with the thumb-nail or écraseur; this can be held by the two last fingers of the hand, and search made for the other ovary, and when found removed in the same manner: when the arm and hand are withdrawn and the wound stitched by the interrupted suture passing through all the tissues except the peritonæum. During the whole operation a twenty per cent. solution of carbolic acid is used with the steam atomizer, the hands and side of the animal being thoroughly washed in the same solution. The hair should be clipped from the flank before incision. The pain from the operation is slight, the cow struggling only during the cutting of the skin, which does not take more than two or three seconds, and again during the sewing at the end of the operation. The latter is the most difficult part of the whole operation, as cow-hide in its undressed condition is very tough. While the arm and hand are within the belly of the cow the animal really seems to enjoy it, acting as a dog does when one rubs his head.

The advantages from this operation are set forth in Mr. Abbott's paper, and I will merely call special attention to a few of the most important. First, the quantity at a milking is increased, and a great increase takes place in the yearly yield of a cow. As to the milk itself, its quality is improved, the fat and sugar are increased, and although I did not keep a record of the examination of specimens of milk from these spayed cows before and after the operations (examining only for my own information, not expecting to have occasion to refer to figures again), I think that, judging from the large number of milk analyses that have been made, I would be supported in claiming that where fat and sugar are increased casein is decreased. Now this milk will be of the same quality day after day, unless the cow has some acute disease, provided she is properly fed and attended to. If over-fed she is apt to fatten, and fall off in the quantity of milk, as a spayed cow, like any animal deprived of the reproductive organs, is quite easy to fatten, thus adding to her value as beef. By this operation all the danger of abortion, post-partum hæmorrhage, accidents during heat, while with the bull, and calving are eliminated. The bad breeding and small cows may be made good milk-producers, and easily fattened for market. But I suppose the greatest advantage of all is the escape of the periodical change occurring in the milk of the unspayed cow every three or four weeks, and lasting a day or two.

Cows are extensively spayed in Texas when young, simply for the purpose of making good beef cattle, the butchers at Brighton abattoir being well aware of this fact. Before operating I visited the abattoir several times for the purpose of becoming acquainted with the anatomy of the cow, and on inquiry at the various slaughter-houses "if they were going to kill a cow" would receive the answer "yes." On the cow being opened I would find only a rudimentary uterus and no ovaries. After examining several I asked the butcher "where the ovaries were." He informed me that they had been removed when the animal was young, and showed me the scar in the hide. The way he had of finding it was that the tissues were all fused together, it requiring care to separate the hide, and the use of the knife, while only his hand was necessary in other parts. It seems to me that this is proof that the operation is a safe one, for the stock-raiser would not run the risk of losing young cattle just for the sake of increasing the weight of a few.

There are two facts which are of interest to us as physicians, namely, first, for two or three days after the operation the flow of milk is reduced to almost nothing. I suppose this is due to the congestion of the broad ligament and tubes. Second, in one case operated on, miscarriage followed ten days after the operation, the calf being macerated so that the hair and skin readily peeled off.

I was present at the spaying of five cows by a veterinary surgeon in which the operation was done through an incision in the posterior and lateral side of the vagina, the surgeon using a speculum to fix the

[1] See Medical and Surgical Journal, No. 14, page 317.

uterus and distend the vagina, then cutting and introducing the hand with an écraseur, and having engaged the ovary removing it and the other through the same opening, the result being left to nature. From the slight observation I have had as yet I would favor the flank operation.

DR. JAMES R. CHADWICK said: I was called upon by Mr. Abbott to operate for him in one of his early cases. I did not find that my previous experience with the human species was of any material aid in the operation upon cows. I can testify that the operation appeared to give the cow but little pain, and only during the incision through the integument and its subsequent suture. The cow seemed to be chiefly affected by alarm at having her head and legs securely bound with ropes, but this no more than equaled our fear lest she should break loose during the operation and strike out. I was surprised on making the incision through the flank to find all further progress apparently barred by one of the stomachs; the hand was, however, easily passed between this and the abdominal wall into the pelvis where the two ovaries were successively seized and torn off by the thumb-nail. But slight hæmorrhage resulted. The only real difficulty of the operation was in perforating the hide with a needle to close the integumental incision. This is readily appreciated by considering the difficulty that would be experienced in trying to sew up a rent in a cowhide boot. Colonel Waring assured me last year that the effect of spaying cows had been of great benefit in promoting lactation, and that the mortality was no greater than five or six deaths in a thousand operations.

DR. GILBERT, of Dorchester, who has also witnessed the operation, said that the cow seemed to suffer no great pain excepting when the outside skin was being cut and when the stitches were inserted at the close of the operation. The risk and discomfort of ether are much greater than the pain of the operation.

DR. MECUEN stated that one cow from which the ovaries were removed has produced milk continuously for eleven years, and in this entire period has fallen off only three pints. Dr. Brush claims that the amount of milk will remain the same during the life of the animal. The carbolic spray was employed in all cases except the first one. On opening the peritonæum the air rushes into the abdominal cavity, but seems to produce no injurious effects. Both ovaries are removed at once. No dressing other than some substance to protect from flies, etc., is necessary, and the wound is entirely healed by first intention in about a week. The animal should be kept on low diet for a day or two, but in three or four days is allowed to run in the pasture as usual. In one case the cow was five months pregnant. The operation produced a miscarriage at the end of ten days. The fruit was macerated. After spaying, the only condition which will cause the quantity or quality of the milk to undergo variation is sickness of the animal.

DR. E. W. CUSHING stated that there is always an infant in his house. He has used the milk from a spayed cow for more than a year and finds it to be a good product and of uniform quality. New milk (after calving) is not good for children, and the milk during menstruation is not wholesome for an infant. Cows and women are much alike in this respect. The milk taken from a pregnant cow is unwholesome for a delicate person, and no mother thinks of nursing her child after she has again become with child. Milk as we obtain it is often neither natural nor healthy, for no animal in a natural condition gives milk while she is carrying her young.

On motion of DR. MARCY a vote of thanks was tendered Mr. Abbott for his description of a safe operation whereby the quality of milk supply may be materially improved and its quantity rendered constant for many years.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

AT a stated meeting of the Society, held March 24th, DR. H. KNAPP read a paper entitled Blindness from Thrombosis of the Retinal Blood-vessels in Facial Erysipelas, with Illustrations, which was discussed by DRS. LORING, HOLCOMBE, and POOLEY.

THE INCORPORATION OF THE SCHOOL OF MIDWIFERY AND THE LICENSING OF GRADUATES IN MIDWIFERY DISAPPROVED.

DR. W. M. CHAMBERLAIN, chairman of the committee appointed at the last meeting to examine and report on the act to incorporate a college of midwifery and the act to regulate the practice of midwifery, presented the following majority report: —

To the Medical Society of the County of New York: Your committee, having carefully considered a draft of An Act to Incorporate a College of Midwifery, also a draft of An Act to Regulate the Practice of Midwifery, and having heard the arguments of the promoters of these acts, are of the opinion that it is not expedient for this Society to indorse or support the said acts.

The question of the conditions under which others than registered physicians shall practice midwifery seems to be an important and difficult one, and in our opinion might properly be referred to a special committee, or to the Comitia Minora, for examination and report.

(Signed)
W. M. CHAMBERLAIN, M. D.,
EDWARD L. PARTRIDGE, M. D.,
ARTHUR M. JACOBUS, M. D.,
CHARLES CARROLL LEE, M. D.

A minority report, as follows, was presented by DR. A. W. WARDEN.

Medical Society of the County of New York, S. O. Vander Poel, M. D., President, W. M. Carpenter, M. D., Secretary: —

The undersigned, a part of your committee appointed to investigate and report to the Medical Society of the County of New York concerning two acts proposed for State legislation, presented to the Medical Society of the County of New York for approval by the promoters of the proposed New York Maternity and School of Midwifery, reports as follows: —

First, In regard to the proposed New York Maternity and School of Midwifery, your committee recommend that the Medical Society of the County of New York *do not indorse* or commend the incorporation of such an institution, because it is not conducive to the elevation of the medical profession and the good of the community.

Secondly, In regard to the proposed act in relation to the practice of midwifery in the State of New York, your committee find such proposed law to be not advisable, and counsel the Medical Society of the County of New York, in the interest of maintaining a high standard of qualification for the practice of midwifery

and all branches of the profession of medicine, and in the interests of the people of the State of New York, that it *do not approve* any State legislation giving the right to practice midwifery, or any branch of the profession of medicine, to persons other than qualified and registered (male or female) physicians.

(Signed.) A. W. WARDEN, M. D.

After considerable discussion the minority report, on motion of DR. E. C. HARWOOD, was adopted.

COLLECTIVE INVESTIGATION OF DISEASE.

On motion of DR. DAVID WEBSTER, chairman of the committee on collective investigation of disease, who reported that the histories of about fifty cases of intestinal obstruction had been sent in, and that their consideration would require more time than could be given to the matter on this occasion, a special meeting for this purpose was appointed for April 7th.

Medical and Surgical Journal.

THURSDAY, APRIL 10, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY, No. 4 PARK STREET, BOSTON, MASS.

INSANITY AND THE LAW.

THE recent sentence to death, in England, of two evidently insane murderers, William Gouldstone and James Coles, for clearly irresponsible acts, and the repeated escape on the ground of insanity, in this country, of sane and responsible men, on trial for cold-blooded murder, of which Nutt is the last conspicuous case, have turned thoughts anew to the question of the responsibility of criminals and the definitions of insanity. Gouldstone and Coles were reprieved and sent to a criminal lunatic asylum, but Nutt is still at large, a free man, and an example to others of the ease with which murder may be committed and the laws defied. It has long been the opinion of leading medical authorities, of Krafft-Ebing, Bucknill, and Gray particularly, that the mental disease of the physician does not necessarily constitute irresponsibility under the law. Lord Bramwell, too, has ruled that insanity is strong but not conclusive evidence of innocence, and Lord Blackburn has stated that the jury must decide in each case whether the disease of the mind or the criminal will was the cause of the crime. In a recent lecture, published in the *British Medical Journal* of March 15th and March 22d, Dr. Bucknill's medico-legal definition of insanity is *incapacitating weakness or derangement of mind caused by disease*, meaning, in criminal cases, inability of abstaining from the criminal act, which would be expressed by Lord Bramwell's criterion, *Could he help it?* Dr. Bucknill suggests, as an amendment to the law of England, that *no act is a crime if the person who does it is at the time incapable of not doing it by reason of idiocy or of disease affecting his mind.*

Of course no ordinary jury is competent to pass upon such a question. Dr. Bucknill quotes Colonel Corkhill's opinion, given soon after the Guiteau trial, "that when a prisoner proposes to defend his crime on the ground of insanity a jury specially selected for their fitness should be chosen to try the special plea, and if the prisoner be found insane then he should be confined in an insane prison for a time commensurate with the character of the crime, and if the verdict of the jury be in favor of his sanity then the plea should not be allowed upon the trial."

With such definitions of insanity and irresponsibility, and such a procedure before the trial, it is probable that many of the differences between the doctors and the lawyers would be met, and that a medico-legal definition of insanity would be found broad enough to cover all cases, and flexible enough to admit of ready application to every one committing an act in violation of the laws. We should avoid, too, such disagreeable complications as occurred during the Guiteau trial, and make it harder for judges and juries to acquit of murder, on the ground of insanity, responsible men who do their killing under circumstances appealing to the sympathies of their community. In our country there is less danger of convicting an insane man than in England, but the danger is greater of allowing sane criminals to escape the penalty of their deeds by a false claim of irresponsibility. Throughout the world criminal jurisprudence follows slowly after the discoveries and advances in medical pathology, and the great advantage of Dr. Bucknill's position is that the law of the land may be administered without being changed every few years to adapt itself to more recent views regarding the nature and limitations of mental disease.

MODERN AND ANCIENT LEPROSY IN SYRIA.

THE intrinsic and historic interest connected with leprosy is such as to make it a fascinating field for research. The recent case at Salem, Mass., is fresh in the minds of our readers, in which the disease was imported from the Sandwich Islands. Descriptions of the leprous community on one of those islands have been frequently given us by travelers. Recently an interesting account has been published by Professor Lortet, dean of the Faculty of Medicine at Lyons, of the disease as observed by him in Syria. These papers may be found in the first few numbers of *Lyon Médical* for the current year. The picture presented is a most revolting one, but inasmuch as it shows the disease as it occurs among a people crowded together and entirely devoid of even that palliative treatment which medical knowledge is able to afford, it may perhaps be taken as a fair representation of that type of the disease which in the Middle Ages followed back the returning Crusaders and spread terror over so much of Europe.

It seems that in Syria leprosy is closely limited to

the southern parts bordering on the Egyptian confine, Neapolis on the north, and Joppa, Jerusalem, and Hebron on the south representing its topographical range. The nomadic Arabs on the shores of the Dead Sea are exempt. The total number of lepers in Syria is given as about two hundred. They are confined to certain cities, where they beg alms during the day and retire at night to their quarters and contribute their gains to a common fund. Until recently they had their "quarter" in Jerusalem, where they occupied a collection of huts made of reeds and mud, so low that it was necessary to crawl into them, and filled with all sorts of filth. Now they are removed outside the wall to a big one-story structure built on a spot partly cut out of the rock above the valley of the Kedron, where hygienically they are about as badly off as before. The several compartments all have their entrances looking against the face of the rock. These rooms are each thirteen feet by twenty-two, and serve each for shelter to a group of lepers, or a family if they are married. The only furniture in these rooms consists of two boxes, one for containing the poor food on which they subsist, the other the rotten rags with which they cover their putrefying sores. The floor is of bare earth with perhaps a few bits of old clothing that they have begged to sleep on. There is no fireplace, but two or three stones are put together when there is wood to burn, and the smoke, with the exception of what is deposited on the walls and roof, escapes through the door and window.

Of the aspects of the disease in its worst forms we have not space to speak in detail, nor would the description be especially novel to our readers. The reddish-purple tubercles on the face, shoulders, and extremities, particularly the posterior surface of the forearm, the inside of the thigh, and the front of the leg; the large yellowish spots which in milder cases replace the tubercles and have a similar distribution; the breaking down into ulcers of these first formations; the extensive areas of superficial anæsthesia; the contraction of the flexor muscles so that the hands cannot be opened, and the toes are drawn down upon the plantar surface of the foot; the ulceration and sloughing of the phalanges one by one, till the metatarsal and metacarpal bones are exposed, protruding from a bleeding, horribly fetid wound; finally, the gangrene attacking the face, the cornea, the ears, and the scalp, and eating its way into the bones of the nose and cranium, — these are among the salient features of the portrait drawn by M. Lortet as well as by other observers of the worst forms of the neglected leprosy of to-day. For the more complete details we refer the reader to the article cited.

The community on the banks of the Kedron is, we learn, governed by a sheik, himself a leper, for whom his subjects show the utmost submission and respect. Lepers can marry only among themselves. Women, being less frequently the victims of the disease than men, are at a premium in the matrimonial market, and command a substantial pecuniary price. The desire for marriage among the men seems to be chiefly based on the hope of securing a nurse against a time when they can no longer do anything for themselves. Either from the frequency of an implication of the organs of generation or from the constitutional depression these marriages are almost always sterile. The disease is eminently hereditary. Out of twenty-six cases which are described in detail by the writer no less than twenty-one were of leprous parentage. While a child of a leprous father may in rare cases escape the malady, there is no authentic instance, according to this author, of a leprous mother failing to transmit the disease, which appears in the child at from eight to ten years, never earlier.

Little is known regarding the cause of leprosy, but M. Lortet points out the interesting fact that all the lepers in Syria are fellahs, that is, mussulman or Christian farmers, whose diet is notably poor, consisting of innutritious vegetables like lentils, with never any meat. The Israelites, and in general the inhabitants of the towns, however insalubrious the surroundings of the latter, are exempt from leprosy. Ichthyophagy, as a cause of the disease, is rejected by M. Lortet, his Syrian fellahs having for the most part no fish to eat. The largely maritime distribution of leprosy, with other facts which have given credit to the theory that ascribes it to a fish diet, are reconcilable with M. Lortet's observations if we suppose leprosy to be in part at least a vice of nutrition, and caused alike whether bad fish or any other innutritious food is made the only diet to the exclusion of adequate alimentation.

M. Lortet believes leprosy to be contagious through the channel of the cutaneous lesions, the lungs, and the digestive tract. He also confirms the view of its parasitic nature, held by many recent observers. He found in sections from non-ulcerated leprous tubercles that the derm was infiltrated with large, irregular cells, multipolar, and filled with long, very slender bacteria, which possessed a very active movement.

The description of leprosy as it exists to-day in the Holy Land suggests, very naturally, the inquiry how far it is identical with the disease called by that name in the Bible. In the thirteenth chapter of Leviticus are to be found the Mosaic rules for diagnosis of leprosy. From these it seems probable that the lawgiver included under that title a number of contagious diseases, among them favus and tinea barbæ (verses 29, 30). While some authorities have denied that the leprosy of Moses included at all the *elephantiasis Græcorum*, others have recognized this as one of the types which he described. In the *Popular Science Monthly* for April Dr. George H. Fox discusses this question. He shows that the expression "white as snow," so frequently applied to the appearance of the disease, does not seem applicable to modern leprosy of either the macular or of the tuberculous type. The direction for the patient to be examined by the priest after seven days for evidence of change in his condition seems to contemplate some disease less chronic in its development than leprosy. It may well be supposed that the practical purpose of Moses' instruction being preventive treatment, the law-giver may have included all contagious skin diseases with which he

was acquainted under one term without specifying or even knowing their diagnostic differentiation.

Regarding the "leprosy" of the New Testament, Dr. Fox points out its probable identity with psoriasis. The Septuagint translators rendered the Hebrew *tsaraath* by the word *lepra*, which was the name of a disease characterized by white scaly patches (psoriasis), and familiar to the Greeks, who, on the other hand, knew nothing of leprosy. Afterwards the true leprosy, the "Phœnician disease," was introduced into Greece, and was called elephantiasis. The word used by the evangelists, Matthew and Mark, in describing the miracle of the Saviour is lepra and not elephantiasis. The translators of the English Bible rendered this word "leprosy," which was also the translation of the Hebrew *tsaraath*, because the Septuagint translators had rendered the latter word by lepra. The inference is clear that the leprosy of the New Testament was psoriasis, and it is not improbable that it was this disease which made some of its subjects among the ancient Hebrews "as white as snow."

LEGISLATION IN NEW YORK FOR THE PROTECTION OF FOOD PRODUCTS.

THE Committee on Public Health have made their report to the New York Legislature in regard to imitation butter, and recommended, as the result of their investigations, that its manufacture should be totally prohibited by law. In the course of it they say: "While not averring that oleomargarine is necessarily always unwholesome, the committee believe that it is likely to be so, and to a large extent would necessarily be injurious if used by children or persons in delicate health, and that it is not in any sense, or can be, a wholesome substitute for pure and natural butter."

In consequence of this report Judge Low's bill "to prevent deception in sales of dairy products," which met with very little opposition, was ordered to a third reading on the 28th of March. This goes to the root of the evil, and prohibits the manufacture or sale of any of these adulterations in the State of New York. All previous legislation on the subject has merely sought to regulate the sale of imitation butter so as to enable purchasers to know what they were buying, but though no less than seven bills for the protection of the people against deception and imposition have been passed by the Legislature during the last five years, all attempts to do this have hitherto proved a complete failure, as was shown by the experience of the Senate Committee on Public Health, which, during its recent sessions in New York, found that the analysis of thirty samples of butter purchased from different grocers in New York and Brooklyn showed that twenty of them were imitations, although they were all represented by the venders to be "pure butter." The bill, as introduced, constituted the State Dairymen's Association a commission charged with the enforcement of its various provisions, and appropriated $30,000 to defray expenses, but it was afterwards amended by substituting for the Dairymen's Association a "dairy commissioner," who should be appointed by the Governor, and receive a salary of $3000 and his necessary expenses. It is stated that such a prohibitory law has worked well in Missouri, and that in consequence of its rigid enforcement a large quantity of imitation butter, manufactured in Chicago, which used to be supplied to that State, is now sent on to New York.

During the week ending March 22d 33,405 pounds of diseased meat and "bob" veal were seized by the inspectors of the Health Department in New York. and Health Commissioner Raymond, of Brooklyn, has made the following order: "In order to prevent the admission of meats of an unwholesome quality into the markets of the city on and after March 26, 1884, no cows or bulls shall be slaughtered in any slaughtering house in the city of Brooklyn except in the presence of an inspector of the Health Department, the owners of said slaughtering establishments to receive notice of the time when said inspectors will be present."

Massachusetts seems to be the only State at present which evinces any marked disposition to progress backwards in these legislative questions for the protection of the public against adulterations of foods and drugs.

MEDICAL NOTES.

— Dr. Fordyce Barker and Surgeon J. S. Billings sailed from New York last week to receive the degree of LL. D. at the approaching tercentenary of the University of Edinburgh. We understand the same honor was offered to other gentlemen connected with the medical profession, but that the necessity for personal presence prevented its acceptance.

— At the annual meeting of the New York Neurological Society held April 1st, William J. Morton, M. D., was elected President, and E. C. Wendt, M. D., Secretary.

— Dr. Wood, editor of the *North Carolina Medical Journal*, is engaged upon an inquiry as to the effects of tobacco upon the human system, with a view to publication, and is glad to receive reports from any reliable medical source.

— The conclusions of an article in review of the treatment of uterine fibromata, in the *Revue Médicale* (9 February, 1884), may perhaps, be taken as reflecting the French sentiment, in this respect. They are as follows: Expectation, too much neglected by the Germans, better respected in England, ought to play an important rôle in the therapeutics of uterine fibromata. Surgical interference ought to be made only in cases which are serious either from pains or hæmorrhages which they produce. In order that the operation be justified the pains must be such as to render life insupportable to the patient, and the hæmorrhages so severe as to expose her to mortal danger. When, finally, the operation is resolved upon, castration is the measure to which recourse should be had in cases where the tumor is not bulky, and ablation, on the

other hand, where the volume of the tumor is considerable.

— An International Prison Congress will meet at Rome next October.

— The Kansas Legislature has been considering a bill for the protection of domestic animals, and also one for establishing an office of State Veterinarian, whose duties shall be to investigate all infectious or contagious diseases, under direction of the Live Stock Sanitary Commission, visiting at once any locality where such disease may be located, establish quarantine, and take other necessary measures. He shall keep posted in all diseases of live stock, and make reports and perform such other service as may be required by law or directed by the Sanitary Commission. A salary of $2500, with traveling expenses, is proposed.

— From the edition of Messrs. George P. Rowell & Co.'s American Newspaper Directory, now in press, it appears that the newspapers and periodicals of all kinds at present issued in the United States and Canada reach a grand total of 13,402. This is a net gain of precisely 1600 during the last twelve months, and exhibits an increase of 5618 over the total number published just ten years since. The increase in 1874 over the total for 1873 was 493. During the past year the dailies have increased from 1138 to 1254; the weeklies from 9062 to 10,028; and the monthlies from 1091 to 1499. The greatest increase is in the Western States. Illinois, for instance, now shows 1009 papers in place of last year's total of 904, while Missouri issues 604 instead of the 523 reported in 1883. Other leading Western States also exhibit a great percentage of increase. The total number of papers in New York State is 1523 against 1399 in 1883. Canada has shared in the general increase.

— We learn from our foreign exchanges that the French Court of Cassation has quashed a judgment obtained some time ago by the proprietress of a hotel near the Sorbonne, awarding damages for disturbance to her trade caused by the howlings of dogs undergoing vivisection at that institution. The court holds that the physiological experiments in question constitute a branch of instruction given by the State, and that M. Paul Bert, against whom the judgment was obtained, and other professors of every rank, accomplish by such experiments a public service.

NEW YORK.

— A communication was received by the New York Board of Health, on March 25th, from the Department of State forwarding a request from the Duke of Buckingham that the Health Department of the city should be represented at the International Health Exhibition in London in May next, and also at the International Sanitary Congress in the same city in June. The Board designated Dr. Woolsey Johnson, Health Commissioner, and Prof. Charles F. Chandler, late president of the Board, as its representatives, and also resolved to call the attention of the Chamber of Commerce and the Board of Education to the matter in order that these bodies might send representatives to the exhibition and congress, and that public interest might be aroused in regard to the same.

PHILADELPHIA.

— The Philadelphia County Medical Society held a stated quarterly meeting for the election of new members April 2d. Among the candidates to be balloted for was the name of a graduate of the Women's Medical College, but who was personally and professionally qualified for membership, and was so reported by the Board of Censors. It was found, however, that the opposition to woman physicians was both strong and active, and she failed to be elected. At this meeting an amendment to the Constitution was voted upon, making women ineligible as candidates for membership, by the introduction of the word "male" before the word "physician," so that Article I. of the Constitution should read "This Society shall consist of regular, *male* physicians, residents of the County of Philadelphia," etc. Out of 127 votes 78 were in favor and 49 against the amendment, which failed of being adopted, as it did not receive a two-thirds vote. The discussion of the question revealed a radical and irreconcilable difference of opinion concerning the functions of a county medical society, one side holding that it was an independent organization, with the right to refuse admission to membership on other than professional grounds, the other maintaining that as a representative body it belonged to the members of the profession in Philadelphia County, whom it claimed to represent; all of whom were therefore entitled to membership. The fact that other counties in Pennsylvania have acknowledged the truth of this principle, and that the New York County Medical Society has adopted it, shows that there are no insuperable objections to its adoption in Philadelphia.

The County Medical Society holds three conversational meetings each month, which are well attended, one or two papers being read at each meeting. The discussion on tuberculosis, inaugurated by Dr. Formad's paper, Is Consumption Contagious, was well sustained and very interesting.

— The State Medical Society will meet in Philadelphia next month (May 14th, 15th, and 16th). Among its members are several woman physicians, one of whom, Dr. Alice Bennett, of Norristown, will deliver the Address on Mental Disorders. Dr. John B. Roberts will read the Address on Surgery; Dr. Jacob Price, of Westchester, that on Obstetrics; Dr. Benjamin Lee, in Hygiene; Dr. W. H. Daly, of Pittsburg, in Medicine, and Dr. William S. Little on Ophthalmology.

— The Jefferson Medical College held its fifty-ninth annual commencement on March 29th, when a class of 215 was graduated, many of whom were third-course students. The matriculates this session were 554, nearly as many as last session. The degree of LL. D. was conferred upon J. M. DaCosta of Philadelphia, and Prof. Benjamin Silliman of New Haven, and that of D. D. upon Rev. J. F. Dripps of Philadelphia.

— The University of Pennsylvania will hold its one hundred and nineteenth annual commencement

May 1st, when about 100 will receive the degree of M. D. The first-year class numbers 140, which is considerably larger than last year.

— The thirty-second annual commencement of the Women's Medical College was held March 13th, when the degree of M. D. was conferred upon twenty-six graduates.

— The Medico-Chirurgical College graduated four at its commencement held April 3d. This college has recently lost its President, Dr. G. P. Oliver, who died suddenly with apoplexy about two months ago, and also Prof. F. O. Nagle, who died February 1st with typhoid fever. It is probable that the school will be reorganized during the summer, and enter upon a larger and more important work under the guidance of a few young, able, and energetic members of the profession.

— A new organization, the Medical Jurisprudence Society, for the cultivation of medico-legal science, has been started, with Prof. Emeritus S. D. Gross, M. D., LL. D., D. C. L., as president. It meets on the second Tuesday of each month (save July and August) at the hall of the College of Physicians. A Clinical Society has also been formed out of the old Northern Medical Association.

— Prof. H. G. Landis, of Columbus, Ohio, who was the orator of the Alumni Association, was the recipient of marked attention while here, and was complimented by a dinner at the St. George Hotel given by the Association.

Miscellany.

AN EPIDEMIC OF TRICHINOSIS.

One of the most extensive and fatal outbreaks of trichinosis in recent years has recently occurred in the district of Magdeburg, an account of which may be found in the December number of the *Centralblatt für allg. Gesundheitspflege*, and also in the *Practitioner* for February, 1884.

"It appears that the flesh of an undoubtedly trichinous pig which had been slaughtered on the 15th of September last at the little town of Emersleben was disposed of on that and the following day in Emersleben and neighboring villages. According to universal custom in Saxony nearly the whole of the flesh was eaten in a raw state as minced meat.

"The earliest cases of illness showed themselves in Emersleben on the 18th of September, and by the 28th of the month the disease was prevalent throughout the place.

"The first symptoms noticeable in the cases were violent diarrhœa and marked loss of strength. The persons first attacked were the family of the butcher who killed the pig, no member of which escaped. The disease was at once recognized to be trichinosis, and upon further inquiry it was ascertained that in every instance pork obtained from the same source had been partaken of in a raw or green-smoked state previous to illness.

"The epidemic continued to augment in numbers until the beginning of October, when also the first fatal case occurred. On examining the muscles of the body numerous trichinæ were discovered, and enormous numbers were present in the contents of the intestine, every preparation of the intestinal mucus disclosing from ten to fifteen trichinæ within a field of the magnitude of a small lentil.

"In subsequent deaths microscopic examination revealed similar results, the numbers of trichinæ in the muscles being less remarkable, however, than the swarms which, including adult forms, were always present in the intestine.

"Up to November 11th there had occurred in Emersleben (a place of 900 inhabitants), 240; in Deesdorf (with 400 inhabitants), 40; in Nieuhagen, 70; and in the remaining localities affected, 11; in all 361 cases of trichinosis, and of these 57 had proved fatal, including 45 deaths in Emersleben and 10 in Deesdorf."

ADULTERATED DRUGS.

The following remonstrance, addressed to the Senate and House of Representatives of Massachusetts, was drawn up by Dr. Henry W. Williams, and, as will be observed, is signed by the President and all the living ex-presidents of the Massachusetts Medical Society: —

The undersigned, physicians of Massachusetts, respectly represent that, in our opinion, the United States Pharmacopœia should be the *only* standard for the preparation and sale of drugs and medicines, and we earnestly remonstrate against any alteration of the present law relating to the adulteration of medicines or of articles of food, believing, as we do, that this law is an important safeguard to the public.

Alfred Hosmer, President of the Massachusetts Medical Society,
George C. Shattuck, Ex-President.
George H. Lyman, Ex-President.
Benjamin E. Cotting, Ex-President.
Henry W. Williams, Ex-President.

The discussion of this subject in the House of Representatives was assigned for Wednesday, April 9th.

FOOT-BALL: THE KILLED AND WOUNDED.

The result, on one day recently, of four foot-ball fights — it is a gross misuse of language to call them "games" — was that two young men lost their lives, and two sustained fractures of the leg, in one instance apparently a severe compound fracture; one of the deaths was said to have been due to heart-disease, the other was clearly caused by fracture of the spine in the neck. It is a great pity that what might be a manly and health-giving game should have been allowed to degenerate into a kind of organized faction fight. The human skull, unlike that of the goat and bull, is not adapted for use as a battering-ram; the death of a young man who perishes in the attempt to emulate the tactics of a goat or a bull may perhaps not be any great loss to the community, but what we complain of is that such conduct should be held up before the eyes of a number of young men and lads as an example to be followed. The constituted authorities of foot-ball ought to be able to make regulations sufficiently stringent to prevent the, at present, high percentage of killed and wounded.

If they want a precedent they have only to turn to the action of the cricket legislature, which is to meet at Lord's next month. in order to pass laws intended to put a stop to certain dangerous abuses which have crept into the noble game. — *British Medical Journal*, March 22d.

REPORTED MORTALITY FOR THE WEEK ENDING MARCH 29, 1884.

Deaths reported 2789 (no reports from Buffalo, Milwaukee, and Providence): under five years of age, 1011: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 419, consumption 418, lung diseases 411, diphtheria and croup 105, scarlet fever 56, diarrhœal diseases 51, measles 43, typhoid fever 34, cerebro-spinal meningitis 25, erysipelas 22, whooping-cough 23, puerperal fever 21, small-pox 18, malarial fever 18, typhus fever three. From *measles*, Baltimore 19, New York 11, New Orleans six, Philadelphia, Brooklyn, and District of Columbia two each, Charleston one. From *typhoid fever*, Philadelphia 15, Baltimore five, New York and Pittsburg three each, Brooklyn, Cincinnati, New Orleans, Nashville, Worcester, Lawrence, and Fairhaven one each. From *cerebro-spinal meningitis*, New York eight, Fall River three, Philadelphia, Cincinnati, and Worcester two each, Chicago, Baltimore, Charleston, Lawrence, Lynn, Haverhill, Brockton, and Fitchburg one each. From *erysipelas* New York seven, Chicago four, Brooklyn and Boston two each, Philadelphia, Baltimore, New Orleans, Charleston, Brockton, Hingham, and West Brookfield one each. From *whooping-cough*, New York six, New Orleans four, Brooklyn, District of Columbia, and Boston three each, Philadelphia, Chicago, Baltimore, and Cincinnati one each. From *puerperal fever*, Chicago five, New York three, St. Louis, Cincinnati, and Lowell two each, Philadelphia, Brooklyn, New Orleans, District of Columbia, Cambridge, Springfield, and Stoneham one each. From *small-pox*, New Orleans 15, Cincinnati three. From *malarial fevers*, New York six, Brooklyn and St. Louis three each, Baltimore and New Orleans two each, Cincinnati and New Haven one each. From *typhus fever*, New York three.

Seven cases of small-pox were reported in St. Louis, Cincinnati two; scarlet fever 43, diphtheria 16, typhoid fever eight, and measles one, in Boston.

In 97 cities and towns of Massachusetts, with an estimated population of 1,149,642 (estimated population of the State 1,955,104), the total death-rate for the week was 22.61 against 18.21 and 17.07 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending March 15th, the death-rate was 22.6. Deaths reported 3796: acute diseases of the respiratory organs (London) 370, whooping-cough 160, measles 146, scarlet fever 81, fever 40, diarrhœa 38, diphtheria 20, small-pox (London 11, Liverpool and Sunderland two each, Sheffield and Newcastle one each) 17. The death-rates ranged from 15.2 in Plymouth to 30.5 in Manchester; Bradford 19.2; Sheffield 19.4; Birmingham 21.1; London 21.6; Leicester 21.6; Nottingham 21.9; Liverpool 22.8; Sunderland 23.7; Leeds 29.8; Birkenhead 29.9. In Edinburgh 21.6; Glasgow 23.3; Dublin 27.4.

For the week ending March 15th, in the Swiss towns, there were 35 deaths from consumption, lung diseases 33, diarrhœal diseases 19, typhoid fever 16, whooping-cough 13, diphtheria and croup 10, measles four, scarlet fever two. The death-rates were, at Geneva 29.6; Zurich 19.7; Basle 20.9; Berne 23.3.

The meteorological record for the week ending March 29th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, JANUARY 1, 1884. TO MARCH 31, 1884.

FESSENDEN, C. S. D., surgeon. To proceed to Cairo, Illinois, and Memphis, Tennessee, as inspector. March 5, 1884.

PURVIANCE, GEORGE, surgeon. Granted leave of absence for thirty days. February 16, 1884.

SMITH, HENRY, surgeon. To rejoin his station at Norfolk, Virginia. March 7, 1884.

IRWIN, FAIRFAX, passed assistant surgeon. Relieved from duty at Norfolk, Virginia; to assume charge of Cape Charles Quarantine Station. March 7, 1884.

CARMICHAEL, D. A., assistant surgeon. To report to Surgeon Purviance for examination for promotion. March 5, 1884.

ARMSTRONG, S. T., assistant surgeon. To report to Surgeon Fessenden for examination for promotion. March 5, 1884.

BENNETT, P. H., assistant surgeon. Leave of absence extended ten days. January 18, 1884.

AMES, R. P. M., assistant surgeon. Detailed for temporary duty on relief boat, — Ohio River flood sufferers. February 16 and March 1, 1884.

DEVAN, S. C., assistant surgeon. Upon expiration of leave of absence to proceed to St. Louis, Missouri, for temporary duty. February 6, 1884.

KALLOCH, P. C., assistant surgeon. To proceed to Charleston, South Carolina, for temporary duty. February 1, 1884.

BEVAN, A. D., assistant surgeon. Granted leave of absence for seven days. March 13, 1884.

WASDIN, EUGENE, assistant surgeon. Granted leave of absence for fifteen days. March 4, 1884.

BATTLE, K. P., assistant surgeon. To proceed to New York, N. Y., for temporary duty. February 4, 1884.

RESIGNATION.

COOKE, H. P., passed assistant surgeon. Resignation accepted by the Secretary of the Treasury, to take effect February 5, 1884. January 31, 1884.

APPOINTMENT.

BATTLE, KEMP P., M. D., of North Carolina, having passed the examination required by the regulations, was appointed an assistant surgeon by the Secretary of the Treasury, February 2, 1884.

PROMOTIONS.

CARMICHAEL, D. A., passed assistant surgeon. Promoted and appointed passed assistant surgeon, by the Secretary of the Treasury, from March 1, 1884. March 18, 1884.

ARMSTRONG, S. T., passed assistant surgeon. Promoted and appointed passed assistant surgeon, by the Secretary of the Treasury, from April 1, 1884. March 28, 1884.

A CORRECTION.

MR. EDITOR, — Through an error in copying the statement is made in the article on Tracheotomy in the last number of the JOURNAL, that *eleven* patients recovered. The facts are as follows: Number of operations, twenty-one; number of recoveries, *ten*. Very truly yours, GEO. W. GAY, M. D.

BOSTON, *April* 5, 1884.

THE ASSOCIATION OF AMERICAN MEDICAL EDITORS. ANNUAL MEETING, WASHINGTON, D. C., MAY 5, 1884. — The annual meeting of the Association of American Medical Editors will be held in Washington, May 5th, at eight P. M., in Medical Hall, southeast corner of Sixth and F Streets. The Annual Address will be delivered by President Leartus Connor, M. D., on The American Medical Journal of the Future, as indicated by the History of American Medical Journals in the Past. Dr. N. S. Davis will open the discussion on How far can Legislation Aid in Elevating the Standard of Medical Education in this Country? in which Dr. A. B. Palmer, Dr. H. O. Marcy, Dr. L. S. McMurtry, Dr. C. H. Hughes, Dr. Frank Woodbury, Dr. William Brodie, Dr. A. N. Bell, Dr. William B. Atkinson, Dr. W. C. Wile, Dr. W. R. D. Blackwood, Dr. Henry Leffmann, and Dr. Deering J. Roberts will take part. All members of the profession, especially journalists and authors, are invited to be present and take part in the meeting.

JOHN V. SHOEMAKER, M. D., *Secretary*.
PHILADELPHIA, 1031 Walnut Street.

MIDDLESEX SOUTH DISTRICT MEDICAL SOCIETY. — The annual meeting will be held at Porter's Hotel, North Cambridge, on Wednesday, April 16, 1884, at twelve o'clock. The Annual Address will be delivered at one o'clock P. M. by Dr. H. M. Field, of Newton. A special dinner will be served at two o'clock P. M. The Censors of the Society will meet at the same place, at 11.30 A. M. of the same day, to consider applications for admission to the Massachusetts Medical Society. The annual assessment should be paid to Dr. J. W. Willis, Treasurer, before the meeting of the State Society. Members may order telephone messages to be sent to No. 7081, and they will be delivered at the Hotel. WALTER ELA, *Secretary*.
CAMBRIDGE, *April* 9, 1884.

ILLINOIS STATE BOARD OF HEALTH. — The regular quarterly meeting of the Illinois State Board of Health will be held at the Grand Pacific Hotel, in Chicago, beginning Thursday, April 17th. At this session candidates for certificates will be examined, both non-graduates, who must undergo an examination upon their preliminary education, as well as in the usual branches of medical study, and also graduates of colleges which have not fully complied with the schedule of minimum requirements adopted by the Board in 1880, and in force from and after the session of 1882–83.

BOOKS AND PAMPHLETS RECEIVED. — Fourteenth Annual Report of the Massachusetts Homœopathic Hospital and of the Ladies' Aid Association for the Year ending December 31, 1883. Boston. 1884.

1883. Annual Report of the Presbyterian Eye, Ear, and Throat Charity Hospital, No. 77 East Baltimore Street, Baltimore, Md. 1884.

Original Articles.

ENTERIC FEVER IN NEW HAVEN.[1]

BY GUSTAVUS ELIOT, A. M., M. D.,
Attending Physician to the New Haven Dispensary.

I HAVE chosen to use the name enteric fever to designate the disease commonly known as typhoid fever, in preference to the latter term, for the following reasons: First, the adjective typhoid has been used to such an extent, in connection with various diseases accompanied by serious symptoms, that its use at the present time is frequently misleading both to the public and to the profession. Second, the name enteric fever is used instead of typhoid fever in the Provisional Nomenclature of the Royal College of Physicians, London, which was adopted in 1873 by the United States Marine Hospital Bureau as the nosological system to be observed by medical officers of the service in their reports and communications. Third, the same name is now frequently employed by medical authors and teachers.

Few diseases which prevail in this vicinity are more terrible than the one under consideration. Selecting as its victims those in the full vigor of early adult life, insidious in its onset, increasing daily in severity, protracted in its course, steadily destructive to the most vital tissues and organs of the body, attended by a liability to the most serious complications, it frequently proves fatal, and even when life is spared it is too often followed by disagreeable sequelæ and protracted convalescence. And yet all this is avoidable if we may believe a recent writer[2] on this subject, who tells us that "enteric fever destroys more lives that could be saved than any other acute disease." If there is any ground for such an assertion, the conditions which govern the occurrence of the disease are of incalculable practical importance. I have therefore ventured to introduce the subject at this time with the hope that the members of the Society may from their personal experience contribute some facts toward the solution of the obscure problem, — *what is the origin of the cases of enteric fever which occur in this city?*

During the later months of the year just ended there were an unusual number of deaths from this disease. In October the newspapers attempted to excite something of a sensation on account of the cases which had been reported up to that time. The Health Officer was interviewed, and proved by statistics that the disease was not especially prevalent, that, in fact, it was rather less prevalent than usual. An eminent surgeon was reported to have reiterated the views of the Health Officer. Numerous other physicians expressed the opinion that there neither had been nor was then an unusual number of cases of the disease. But in spite of mathematical proofs and favorable prophecies the mortality report for November indicated that there had been nine deaths from "typhoid fever," — a larger number than had been reported in any one month for ten years.

The existence of conflicting opinions, and of a divergence between opinions and facts, would seem to indicate the desirability of an inquiry into the comparative prevalence of the disease in this and preceding years. With the aid of the Statements of Mortality, published monthly since July, 1874, by order of the Board of Health, I have prepared the following tables: —

I. NUMBER OF DEATHS FROM "TYPHOID FEVER" FOR EACH MONTH SINCE JULY, 1874.

	1874	1875	1876	1877	1878	1879	1880	1881	1882	1883	Total.
January	–	3	2	3	1	–	–	1	2	3	15
February	–	4	–	2	1	–	–	1	2	2	12
March	–	1	3	1	–	–	1	2	–	–	8
April	–	6	1	–	1	4	3	2	2	1	19
May	–	2	1	–	–	2	4	–	–	1	10
June	–	1	1	–	–	1	2	1	–	–	6
July	7	–	3	–	1	1	1	3	–	2	18
August	5	3	6	1	2	1	2	1	5	6	32
September	5	6	3	–	3	–	2	1	4	3	27
October	7	2	1	3	–	–	–	4	1	4	22
November	5	5	1	1	–	–	–	4	4	9	29
December	–	3	–	2	4	1	1	7	3	2	23
Total	29	36	22	13	13	10	16	27	23	33	221

This table indicates that the greatest mortality from enteric fever in New Haven, during the last ten years, occurred in 1874–1875; that the fewest deaths occurred in 1877, 1878, 1879 — fewest of all in 1879; and the mortality during the last six months of 1883 was greater than during any other period of six months since 1874.

Since June, 1877, a considerable number of deaths from typho-malarial fever have been noted in the monthly statements. They are included in the next table: —

II. NUMBER OF DEATHS FROM "TYPHO-MALARIAL FEVER" FOR EACH MONTH SINCE JUNE, 1877.

	1877	1878	1879	1880	1881	1882	1883	Total.
January	–	–	1	–	–	1	–	2
February	–	1	–	–	1	–	2	4
March	–	1	–	1	–	3	–	5
April	–	–	–	1	1	–	–	2
May	–	–	1	3	1	–	–	5
June	4	–	–	5	1	–	1	11
July	1	1	2	4	2	1	1	12
August	–	1	3	3	1	2	1	11
September	–	1	1	3	5	6	1	17
October	–	1	5	3	–	1	1	11
November	6	1	–	4	1	3	1	16
December	1	–	–	2	–	–	2	5
Total	12	7	13	29	13	17	10	101

If we may judge from the opinions expressed in public and private by some of the practitioners of this

[1] Read before the New Haven Medical Association, January 21, 1884.

[2] Wilson, A Treatise on the Continued Fevers, page 221.

city, the term typho-malarial fever is used by them in a somewhat different sense from that generally understood by the profession. Some apply the name to febrile affections of purely malarial origin which present a certain train of symptoms. Others make use of the term to designate a specific disease distinct from enteric fever on the one hand and from fevers of purely malarial origin on the other. Either of these views is equally untenable when examined by the light of recent literature. The name typho-malarial fever was proposed in the summer of 1862 by Dr. J. J. Woodward, Surgeon United States Army, "to a Board of Medical Officers who were directed to revise the form of sick report in use in the army," to designate the "hybrid forms" of fever "resulting from the combined influence of malarial poisoning and of the causes of typhoid fever" which then prevailed in the Army of the Potomac. In September, 1863, Dr. Woodward, in a circular of the Surgeon-General's office, made a statement of the meaning he designed to attach to the term; and in November of the same year he presented his views upon the subject at some length in the Outlines of the Chief Camp Diseases of the United States Armies." In 1876 he professed to hold "substantially the same views," although at that time he frankly confessed that during his earlier studies he had fallen into "some errors of details (particularly with regard to the pathological anatomy of the intestines in these forms) which were incorporated in the account presented in the book on Camp Diseases." "During my earlier studies," says Dr. Woodward, "I believed that I had observed certain peculiarities in the character of the ulcers in these cases, by which they might be distinguished from the lesions of simple typhoid. A larger experience, especially the examination of a large number of specimens received by the Medical Section of the Army Medical Museum, has convinced me that this opinion was premature. I renounce it as erroneous. There is really nothing in the lesions of Peyer's glands, in these cases, to distinguish them from ordinary cases of typhoid fever." Such an unequivocal and impartial statement leaves little doubt as to where Dr. Woodward stands on this question. These views he expressed at the International Medical Congress in Philadelphia, 1876. To show that he does not stand alone in adherence to these opinions it is only necessary to quote a resolution adopted by the Section of Medicine of that Congress, as expressing the opinion of the Section, to this effect: "Typho-malarial fever is not a specific or distinct type of disease, but the term may be conveniently applied to the compound forms of fever which result from the combined influence of the causes of the malarious fevers and of typhoid fever." All recent writers are, so far as I know, of the same opin-

ion. I need only quote Flint, than whom no author in this country is more extensively read or more implicitly trusted, who says: "Typho-malarial fever is caused by the combined action of malaria and the special cause of typhoid fever."[1]

Much of the present confusion in regard to the nomenclature of prevalent febrile affections is due, I believe, to the description of typhoid fever as given by Liebermeister and followed by many later writers. These descriptions led students to expect to find the febrile movement advance with almost mechanical regularity. When in practice they found a disease which manifested all the other symptoms of typhoid fever as they had learned them, but in which the range of temperature did not correspond very closely to what they had learned, they at once set to work to find some cause for what seemed not to belong to the disease. Here, as in numerous other instances, malaria was made the scapegoat, and was forced to bear this along with many other equally undeserved burdens. I do not deny that occasionally the two poisons may exist in the body together and produce, each its characteristic effects simultaneously. But, on the other hand, I am strongly of the opinion that in the majority of doubtful cases, even where the disease is ushered in by a single or repeated chills and by a rapid rise of temperature, it is more reasonable to believe that the peculiar symtomatology of any particular case is due to a normal though perhaps an unusual manifestation of the typhoid poison than to assume that it is due to the existence within the body of the patient of a poison whose presence it is impossible to prove.

In view of these circumstances, and to more accurately indicate the mortality due to the typhoid poison, I have constructed a third table based upon the total number of deaths from the two diseases for each month of the last six years. (See Table on page 363.)

The same facts so far as they relate to the last four years I have also represented by the graphic method given in the above diagram.

These tables — assuming that the causes of death are always correctly reported — do not indicate such an unusual prevalence of enteric fever during the past

year as one would have been led to expect from the number of cases which have been reported in the daily press. Perhaps one reason why the disease has recently attracted especial attention on the part of the public is on account of the social importance of its victims. Another reason why at the present time it unquestionably should command the attention of the profession is the fact that cases of the disease have been reported in nearly all of the neighboring towns, whence are derived the water and milk supplies of the city. It will be instructive to observe during the coming year whether the occurrence of the disease can in any case be traced to infection from either of these sources.

ST. MARY'S LYING-IN HOSPITAL.[1]

BY BENJAMIN CUSHING, M. D.

THE St. Mary's Infant Asylum and Lying-In Hospital, Bowdoin Street, Dorchester, in care of the Sisters of Charity, was opened in September, 1874. To this date, January 8, 1884, during nine years and four months, there have been in the lying-in room 550 patients, a yearly average of about fifty-eight. Married women, twenty. Single, 530. Of the married, one was delivered of her eighth child, one of her fifth, three of their third, and one single woman (colored) of her second. As to ages, two were fourteen years, one thirteen years six months, and the others of ages from fifteen to thirty-eight years. Presentations other than of the head were one of the hand, and several, I do not know exactly how many, of the breech and of the cord. One case of twins. One case of convulsions. In the case of hand presentation the child was turned. Forceps have occasionally been used. One woman (married) was in consumption when she came to the house. A week after delivery, by her own wish, she was taken to her home, where she soon died. One young woman (single) on the tenth day after delivery, was taken away by her friends, and died under circumstances unexplained. The patient who had convulsions was a young woman who had received an education above her social position. She had been led astray and deserted. She came to the hospital with the impression strongly fixed on her mind that she should die. I saw her in the early stage of labor, and as it seemed that there would be some hours to spare I left her for a time to visit other patients. When I returned I found that she had had convulsions, and been delivered with forceps by a physician who had been called in my absence. She had no convulsion after my return, but profuse hæmorrhage. This was stopped, but the next day she had peritonitis, with great tenderness of the abdomen. She died within the week. No post-mortem. Cause of peritonitis, therefore, not known. After her death the room was cleared and cleaned, and the walls were whitewashed. All bedding was either burned or disinfected by boiling or exposure to fumes of burning sulphur. The persons and clothing of all attendants were disinfected. No case of labor was allowed in the house for three weeks. There was no second case of puerperal fever.

There has been no other death among the lying-in women since the hospital was opened. A very good record, I think. I regret that notes of all the cases in detail have not been kept, but as, for various reasons, this has not been done, I give only such facts as may be relied on as correct. Statistics carefully gathered from well-kept notes are doubtless the most valuable contribution to our general knowledge, but impressions, the result of experience, are, I think, not without their value.

It will be interesting to note some of the circumstances under which these 550 labors have occurred.

The house is an old one, built of wood, before furnaces were in use, and, therefore, with open fire-places. It is L-shaped, having two stories, with a French roof, superadded by the Sisters, which makes it really three stories.

In this third story is the children's dormitory, and a room for infants, also one small room used when it is desirable to isolate a patient.

The hall, with stairway, is in the wing of the building. The lying-in room, in which are four beds, is also in the wing, on the second floor. It is a room eighteen feet by sixteen feet, with bath-room attached. The lying-in room and a small room adjoining are warmed by open fires. There are two windows on the south side, and one on the north. Kitchen in the basement. Wash-room adjoining. Sewage into cess-pools. The whole house covers an area of not over 1500 square feet.

Number of occupants: Sisters, six; hired women, two; children, thirty to fifty; infants, twenty to thirty; women waiting, in the beds, and convalescent, twenty-five, more or less. There have sometimes been as many as one hundred persons in the house, including all ages; seldom or never less than eighty. I should add that the nearest building is not less than one hundred feet from the house.

We have had children in the house, from time to time, sick with diphtheria, scarlet fever, measles, and the usual diseases of summer.

One of the Sisters superintends the lying-in room. The nurse or midwife has herself been a patient. The Sister, by the rules of her order, is not allowed to put her own hand to the special work of the nurse.

From September, 1874, to March following I attended all the patients myself as I would in private

[1] Paper read at a meeting of the Dorchester Medical Club, and communicated, by request, to the Obstetric Society of Boston, January 10, 1884.

practice. Since that time several of the Dorchester physicians have been in attendance when called on. I say when called on, for most of the women have not been attended in labor by any physician, the nurse and Sister managing this themselves unless there is especial need of help. Should the labor be tedious, the presentation not understood, should there be hæmorrhage, retained placenta, or any complication calling for help, the physician is sent for.

The usual course pursued is this: At the proper time the nurse examines the patient, and if she feels the head distinctly she infers that all is right. She waits until the child is born, and, after tying the cord and removing the child, lays her hand on the fundus, and follows the uterus as the placenta is expelled. She never introduces the hand to take it. If this is necessary she sends for the physician, but it is very rarely needed. The perinæum is not supported. Ether is not used unless especially indicated, and then only by the physician. Persulphate of iron, ergot, brandy, ether, and a hypodermic syringe are always at hand. The Sister understands their use. After the child is born and the placenta expelled the mother is left undisturbed for an hour, sometimes longer. Not until she is rested is the bed cleared and the binder applied. The after-treatment is simple. For the last few years vaginal injections of Labarraque's solution, largely diluted, have been used for a week, more or less, according to circumstances. The bowels are generally moved on the third day by castor-oil. Of course cleanliness is enforced. Cold water to drink *ad libitum*. Simple diet. All may be summed up in two words, non-meddlesome midwifery.

Thinking of these facts I am confirmed in the impressions which more than thirty years' experience has fixed on my mind, namely, that labor, *as a rule*, is a natural, healthy process, not to be interfered with or helped, only waited on, although I well know that there are many exceptional cases which tax all the resources of the best instructed; that the duty of the physician is to stand ready for emergencies; that we, all of us, are too ready to interfere where interference is worse than useless.

I have lately read, in a New York journal, an article written by a teacher of high authority, in which he gives a formidable list of what the accoucheur should take to the lying-in room. I have not the journal at hand, but recollect that the writer says we should go as to a "capital operation." I at first, by mistake, read it "capital punishment," and I must believe, if thus equipped, this would be the truer word.

AN EPIDEMIC OF TYPHOID FEVER AT A SUMMER HOTEL.

BY L. F. WOODWARD, M. D., WORCESTER, MASS.

THE Black Mountain House, which was destroyed by fire February 17, 1884, was situated in Camptonville, twelve miles north of Plymouth, N. H. It contained accommodations for one hundred and twenty-five guests, and was crowded throughout the whole of July and August.

There had been no sickness until the latter part of July, when a little girl was brought to the hotel with what proved to be a mild case of typhoid fever, hardly severe enough to keep her in bed. She recovered perfectly, and returned home August 30th. No precautions were taken to disinfect the stools, and the other guests were not informed of the nature of the disease. August 30th some of the guests had been complaining for several days of headache and malaise. During the next few days ten of them came down with symptoms of typhoid fever. The hotel was immediately closed, and all that were able to travel were sent home. Four of the guests, however, were too sick to be moved. One of these developed cerebro-spinal meningitis, and died after an illness of eight days. Two of the others, a brother and sister, remained in Campton until the end of the second week, when they were removed to their home in Haverhill, upon beds, without any serious consequences following. The last of the four remained in Campton until she recovered.

The rest of the guests separated in all directions. One party *en route* for Savannah only reached New York, where two of their number went to the Roosevelt Hospital, one with typhoid fever, the other with cerebro-spinal meningitis.

Another lady, living in New York, could only reach Worcester, and was obliged to remain there for several weeks with typhoid fever.

One Boston family had three out of five members sick.

A Newport family had four out of five ill. Of the two Taunton families one had three out of four, the other four out of five, members down with the same complaint.

A Providence family of four had three members sick. One young lady died of typhoid fever in Boston, and four others were sick with the same disease in different cities. Four of the servants of the Black Mountain House were also sick.

In all there were thirty cases of typhoid fever, with one death, and two cases of cerebro-spinal meningitis, with one death.

As far as I could learn, the district had been free from epidemics of typhoid fever for several years, and there had been no case of this disease in town during the summer. The record of deaths in the village shows only one death from this cause in fifteen years.

A careful examination was made of the hotel, water supply, milk, and vaults. The water used came from a spring situated on a hill, one half mile from the hotel, and one quarter of a mile from the nearest dwelling. The spring is on higher land than any of the houses in the village, and the water was carried to the hotel through wooden pipes, with a fall of about one hundred feet.

Occasionally a small quantity of water was used from a neighbor's well, about one hundred and fifty yards from the hotel, and within fifty feet of a dwelling. The milk was either furnished by cows kept in the hotel stable or from a farm in the neighborhood where there had been no sickness.

The hotel itself was built on a sandy soil, and was situated in a high valley. The privy contained no vault, the discharges being allowed to fall upon the surface of the ground. Loam was thrown in upon them twice a day. The liquids soaked into the soil. The solids were shoveled out as often as necessary. There was no drain or cess-pool, and all liquids from the house drainage were also allowed to soak into the ground in the immediate neighborhood of the hotel. Still, although the house was crowded to its utmost capacity, there was no sickness until a case of typhoid fever was

imported. No care was taken to disinfect the discharges of this patient, and they were thrown into the common vault. The result was, that in about four weeks thirty cases of the disease occurred among the guests of the hotel.

The conditions for a typhoid epidemic being so well fulfilled, it would be exceedingly interesting if we could find the vehicle by which the contagion was conveyed. But here we can only exclude the most common, namely, water.

Dr. L. P. Kinnicutt, of the Worcester Free Institute, made analyses of the spring and well waters, and found both pure and free from contamination with fæcal matter. The result of his analysis is as follows: —

Chlorine 2.3 mg. in litre, or 0.2 parts in 100,000.
Free ammonia, .003 mg. in litre, or 0.03 parts in 100,000.
Albuminous ammonia under 1 mg. in litre, or .1 part in 100,000.

Series of cases like the above are interesting in showing how, under favorable circumstances, the neglect to disinfect the discharges of a single patient may give rise to an epidemic.

The sick guests separated in all directions and carried the disease into twelve different cities and towns. Whether they in their turn spread it still further I have been unable to learn.

RECENT PROGRESS IN DISEASES OF CHILDREN.

BY T. M. ROTCH, M. D.

PAVOR NOCTURNUS.[1]

Dr. Oscar Silbermann, after carefully reviewing the opinions of those authors who have written about the "night terrors" of children, finds the greatest diversity of views expressed concerning the ætiology of the disease, some contending that it is an irritation of the cerebral substance, and others a disturbance of digestion, which produces a certain group of symptoms, best represented, however, according to the investigations of Silbermann, by the general term "pavor nocturnus" provided that we recognize two forms of the disease, namely, an idiopathic and a symptomatic pavor nocturnus. By idiopathic pavor we understand a disease *sui generis*, originating primarily in the brain, and running its course in the central organ of imagination (cortical substance). The symptomatic pavor is a reflex neurosis characterized by dyspnœa and anxious crying, and especially caused by irritation of the vagus. The former is the most frequent, and attacks children between the ages of two and six who are delicate and easily excited, but mentally bright. The symptoms are somewhat as follows: After the child has eaten its supper with a good appetite, has gone to bed, and has slept for two or three hours, it awakes with a cry, sits up in bed with wide-opened eyes, and wrings its hands or wards something off with them; its face is often very red and covered with perspiration; the respirations and pulse are somewhat accelerated; the temperature is normal. The child is unconscious, and does not heed the soothing words of those who are around it. After ten or twenty minutes it becomes quiet, begins to cry, recognizes its friends, asks for a light, and then usually goes quietly to sleep, and in the morning has no recollection of what has occurred. No organic cause can be found for this group of symptoms, and it is rather to be sought for in the impressions made on the child's mind during the day. Anæmia, rachitis, and other constitutional anomalies are doubtless predisposing causes, but often fail to be found, the conspicuous feature of the disease always being an expression of fright. Dread may be objective or subjective, and there seems to be no doubt but that in the idiopathic form of this disease it is objective. The symptomatic pavor is usually found among children who are strong and are free from constitutional disease, and from a nervous temperament, some indiscretion of diet appearing to be the cause of a group of symptoms described as follows: The child eats its supper and goes to sleep as usual, but is soon noticed to be very restless, cries out, grinds its teeth, sucks its mouth, its eyes are half closed, and at times it breathes long and deeply. After this uneasy sleep has lasted for an hour or two it wakes up with an anxious cry, suffers from dyspnœa, and utters short interjections as ah! ah! instead of the words representing the object of its imaginative fear as in the idiopathic pavor. The attack does not last so long as in the other form. The pulse is irregular while the dyspnœa lasts, and then the child goes to sleep again, but is usually restless for the rest of the night, and the attack may recur several times in the same night. These children are also very apt to complain in the night of pain in the epigastrium, and on the next day to be found with a coated tongue, some fetor of the breath, and, perhaps, an attack of vomiting or diarrhœa. As in the other form there is no recollection of the attack on the following day.

An analysis of this second form of attack shows that it comes on slowly, gives premonitory signs of its approach, and lasts a shorter time, two to six minutes, the idiopathic form being sudden in its onset, and lasting from ten to forty minutes. The fear in the symptomatic form is evidently caused by the dyspnœa, and the dyspnœa and irregular pulse by irritation of the vagus. Silbermann then reports eleven cases: of these two were three years old, three four years, two five years, two six years, one seven, and one eight. As a summary of his article he presents the following conclusions: (1.) There is a well-marked distinction between the idiopathic and symptomatic forms of pavor nocturnus. (2.) While fear is common to both it is in the idiopathic form objective, and in the symptomatic subjective. (3.) The idiopathic pavor is a disease *sui generis*, characterized by a transitory hallucination expressing objective fear, caused by abnormal irritation of the brain, and always accompanied by a defect of memory. (4.) The symptomatic pavor is a reflex neurosis from the gastric fibres of the vagus to the pulmonary terminal fibres, thus causing dyspnœa and expressions of subjective fear; we here also have amnesia.

INCUBATORS.

A. Auvard,[2] interne at the Maternité in Paris, has written a paper on this subject, entitled, De la Couveuse pour Enfants, a review of which with illustrative plates is to be found in the March number of the *Edinburgh Medical Journal*. The writer describes the incubator devised by Professor Tarnier and used for two years in the Paris Maternity. It consisted of a chamber for containing the child, fixed over a reservoir of water kept always at a suitable temperature. This was considered

[2] Archives de Tocologie, 1883.

too cumbersome for private practice, and Auvard substituted a more simple form, consisting of a wooden box with a shelf in it, on which the child is placed. A sliding door at the bottom of the box allows the introduction of hot water bottles beneath the shelf, and another small sliding door permits fresh air to continually enter the box. A wet sponge keeps the air moist, and the hot air passes out at the top of the box by an aperture which may contain an indicator, and a glass window at the top of the box by opening and shutting is used to prevent the air from getting too hot. Three hot water bottles filled with boiling water are placed beneath the shelf, and in half an hour the temperature will be about 32° C. In two hours a fresh bottle is added, and afterwards, every hour and a half or two hours, the cool bottles are replaced by hot ones. Budin, in La Charité Hospital, uses an incubator heated by gas which has a Regnard's regulator and an electric bell alarm to draw the attendant's attention to any undue change of temperature. Winckel has employed permanent warm baths, and Auvard admits that these are somewhat more effectual than the incubator for cases where there is a decided diminution of the bodily temperature. Full directions are given in the paper for the feeding, clothing, and care of the infants treated in the incubator, which should be referred to by those who wish to employ this method of treatment. As to the results obtained, Dr. Auvard divides the cases, numbering 151, that have been treated, into two classes: first, all children with an initial weight of less than 2000 grammes (roughly four and one half pounds), and, second, children born in a weakly condition from such causes as syphilis, cardiac malformations, œdema, etc. Cases of the first class alone are capable of comparison with children brought up in the ordinary way, and of these a few examples are given. A child of six months and six days intra-uterine life, and weighing 1720 grammes, was kept for forty-six days in the incubator, at the end of which time it was taken out alive and healthy. A child six and one half months, and weighing 1820 grammes, was kept in the incubator five days and was then taken out well. With like result a child of 1630 grammes was kept in eleven days, and a child of 1530 grammes nine days. A seven months' child, weighing 1400 grammes, was taken out in good condition after twelve days in the incubator. In reply to the objection that children of even 1100 grammes have been reared by ordinary means, Dr. Auvard says that such cases are extremely rare and have resulted satisfactorily chiefly from the immense amount of care and trouble that have been bestowed upon them, trouble which is reduced to a minimum by the use of the incubator. He gives the following statistics to prove the value of this method, and the table shows strikingly the value of the incubator for premature children: —

INFANTS WEIGHING LESS THAN 2000 GRAMMES AT BIRTH.

INTERRUPTED PSYCHICAL DEVELOPMENT.[1]

The following abstract in the *American Journal of Obstetrics* is taken from the Nineteenth Report of the Hospital at Berne, where Professor Demme prefaces his clinical report with a statement of the normal development of the power of standing, walking, speaking, and thinking. His conclusions are drawn partly from the works of Vierordt, Kussmaul, and Preyer, partially from his own experience. He finds that (*a*) very strongly developed sucklings will balance the head well in the twelfth or fourteenth week; (*b*) children of medium strength in the fourteenth to sixteenth week; and (*c*) weak children in the eighteenth to twenty-second week. That (*a*) can stand, when supported, in the thirty-fifth to thirty-eighth week, and entirely alone in the fortieth to the forty-second; (*b*) not till the forty-fifth or forty-eighth week; and (*c*) in the first part of the second year. Children who have older brothers and sisters learn to walk much earlier than those who have none, earliest at the end of the ninth month, often between the twelfth and eighteenth month. Children begin to speak at the end of the first or beginning of the second year, — boys later than girls, — and to relate what they have seen or done only at about the end of the fourth year. Demme's clinical observations included cases in which a normally advancing development was interrupted suddenly by some acute disease and afterward advanced again rapidly enough to make up for the lost time, and those in which, under the influence of acute disease, there were abnormalities of development.

(1.) A boy of good size, born asphyxiated, developed normally until the end of the fifth month. He then began to sleep a great deal, was apathetic, and up to the end of the year there was an absolute stand-still in mental development. He then became brighter, played, laughed, and cried like a normal child, began to make rapid progress, in the fourteenth month could sit up, in the eighteenth could stand, and in the twenty-seventh could walk well. There had been no pause in the physical growth. He did not speak until the end of the third year and then only in whispers, but from then on the speech rapidly improved. At the end of the fourth year there was again a disturbance of speech and a return of the sleepiness; but this passed off in a few months, and from that time the child made good progress.

(2.) A large boy of healthy parentage, developed normally till the end of the third month. From this time he had tremors of the hands, the feet, and later of the whole body, with slight opisthotonous and stiffness of the neck. No fever. His mental development was at a stand-still, and he had permanent flexure of the upper extremities. In the forty-fifth week the attacks were less frequent, in the forty-seventh they ceased, and then the intelligence seemed again to waken. At the end of five years he was about as far advanced as an ordinary child of three years. Professor Demme states that early in the boy's life the parents had given him a good deal of opium.

(3.) A strong boy of healthy parentage, developed normally to the fifth month; his father then discovered that he could not distinguish sweet, bitter, salt, or sour by the taste, and that the strongest and most offensive odors had no effect on him. His sight, hearing, touch, and physical development were normal. At the end

[1] American Journal of Obstetrics, October, 1883.

of two years taste and smell were still entirely wanting. The child had a wonderful appetite and would devour large quantities of the most offensive things. In the thirtieth month he had a severe attack of scarlatina which lasted two months. After this the speech was very slow, monotonous, and finally completely aphasic. Hearing was very acute. The aphasia lasted three weeks, and it was several months before the child spoke as well as before the fever. It was then found that taste and smell were normal, and the ravenous appetite had disappeared.

(4.) Was a case of club-foot where, from the fifth to the seventh month, there were occasional right-sided convulsions, with loss of consciousness, opisthotonos, etc. After this the intelligence of the child developed very slowly, but at the age of seven years he was about as far advanced as a child a year or two younger.

ALBUMINURIA IN CHILDREN.[1]

M. Leroux, as the result of researches on the urine of 118 girls and 212 boys in the Hospice des Enfants Assistés, has found that in the case of children affected with marked albuminuria the qualitative alteration appeared pretty constant and independent of the time of the examination, while where there was only transitory albuminuria he found that it was in the afternoon between one and three o'clock, that is to say, after a full meal, the reagent at this time producing a more or less marked reaction, whilst equally fresh urine in the morning only gave negative results.

CONGENITAL MALARIA.[2]

Dr. W. T. Taylor reports the following case, which is of interest in connection with the abstract of Dr. Leroux's article which appeared in the *Boston Medical and Surgical Journal*, January 25, 1883. Mrs. A. R. during her second pregnancy was affected with malarial fever, and although she was then residing at the seashore was obliged to take occasional doses of quinine to control it. She returned to her city residence at the end of the season, and continued using quinine from time to time until the end of her gestation, which was completed in November, 1883, when her infant was born. Her labor was natural and easy, and she had no unfavorable symptoms. The infant appeared healthy and was of good color, but was smaller and more feeble than her first-born had been. The baby soon drew the breast vigorously, as there was a plentiful supply of milk. About one week later the nurse called Dr. Taylor's attention to the fact that the infant occasionally had attacks characterized by coldness of the skin, feeble circulation, and prostration, which continued for fifteen or twenty minutes and were followed by a clammy perspiration. The application of heat to the body and giving it a little brandy and water would revive it. These symptoms appeared to have a periodicity occurring every two or three days, and as they were considered malarial quinine and valerianate of iron were given to the mother, which soon caused the symptoms to cease, and the baby became well and fat. The infant also took small doses of the elixir of cinchona for several weeks. Dr. Taylor considered that the disease must have been contracted in utero, for the infant was born in a perfectly healthy locality where it had not been exposed to any external malarial influence. When labor began the quinine was stopped and was not resumed until the condition of the infant required it, when it quickly arrested the symptoms, and the patient is now perfectly well. Dr. R. P. Harris reports a similar case to the above, where the infant was also treated through the mother's milk with quinine.

[2] New York Medical Journal, March 15, 1884.

TRISMUS NASCENTIUM.[3]

Dr. J. F. Hartigan has written an exhaustive article on this subject, based on a series of 229 cases and numerous post-mortem examinations, in which, after stating the views of the many authors who have described the disease, he says that there is a remarkable uniformity in the pathological appearances found at the autopsies, namely, a congestion of the brain or spinal column (more commonly the latter) or both, with extravasation, and there was no other lesion observed internally except engorgement of the lungs. These results were so marked that it seemed to the author as if some violence or mechanical cause was required to produce them, and directed his attention to the theory promulgated by Dr. J. Marion Sims over thirty years ago, and held by him up to the time of his death, that trismus nascentium was caused by undue pressure of the occipital bone on the brain, and it is this theory which Hartigan endeavors to prove to be correct by additional facts which have come under his notice. In his analysis of the different causes for the disease cited by writers on the subject he shows that their theories are most diverse and contradictory, and that the two which are most worthy of mention are irritation from the umbilicus at the time of the separation of the cord and the above-mentioned pressure of the cranial bones. A large amount of evidence is brought forward by its author against the theory of umbilical irritation, such as the absence of any anatomical lesions which point to the umbilicus as the origin of the disease; the occurrence of cases where the umbilicus is in an abnormal condition and yet no trismus appearing — evidence showing that while there may be such a thing as tetanus due to injury of the umbilicus yet this is not trismus nascentium, and that the latter can scarcely ever be traced to disease of the umbilicus. Hartigan agrees with the statement made by Dr. Sims in his second paper on this subject published in 1848, "that trismus nascentium is a disease of centric origin, depending on a mechanical pressure exerted on the medulla oblongata and its nerves; that this pressure is the result, generally, of an inward displacement of the occipital bone, often very perceptible, but sometimes so slight as to be detected with difficulty; that this displaced condition of the occiput is one of the fixed physiological laws of the parturient state; that when it persists for any length of time after birth, it becomes a pathological condition capable of producing all the symptoms characterizing trismus nascentium, which are relieved simply by rectifying this abnormal displacement and thereby removing the pressure from the base of the brain."

He also describes a class of cases called chronic trismus, where the displacement is very slight, and cases where an opposite condition of affairs exists, namely, where by prolonged lateral decubitus, the occiput being exterior to the parietal bones, the latter are pressed inward. Hartigan divides his reported cases into three classes: (1) those that recovered under postural treatment; (2) cases in which post-mortem examina-

[3] American Journal Medical Sciences, January, 1884.

tions were made, many of which were seen before death but too late to render any service; (3) those whose history was obtained after death, the majority also having been seen before fatal results ensued but where post mortems were not permitted. The table showing the record of 229 deaths was made up of cases under a month old, and there were 150 post mortems.

An analysis of these cases shows that the disease occurs as frequently in the winter as in the summer, that sex had nothing to do with the disease, that the colored element largely predominates, and that no identity exists between this disease and tetanus in the adult. The shortest duration of the disease was one hour, the longest thirty days. The author then proceeds to describe the mechanism of the pressure theory. Before birth the child's head has for its pillow the soft cushion of the liquor amnii. At birth, and for some time subsequently, the cranial bones are not united, are thin, and are without diploë. It is reasonable to suppose that the transition to a different usage will cause them to be easily displaced or the occiput to be depressed, the degree and character depending upon position or management. The child may be retained in the recumbent posture on a hard mattress, or a bunch of clothes, as Dr. Sims says, "wadded up and stuck under the occiput," and interesting cases are cited where removal of these exciting causes occasioned immediate relief from the urgent symptoms. It is not always necessary to the development of the disease that the displacement of the cranial bones should be marked or visible, for from continued decubitus unpleasant symptoms may arise which subside when the child is taken up, and recur again when it is laid down. Dr. Baldwin has claimed that the variations in the post-mortem appearances are not consistent with Dr. Sims's theory, but these are explained by the varying degrees of pressure. In all cases there was congestion of the posterior part of the brain or cord or both. In rapid cases there were coagula in the upper part of the canal in the cavity of the arachnoid, these coagula being sometimes absent in cases so rapid that death was really caused by asphyxia, as shown by congestion of the lungs, etc. In some cases the postural treatment is not sufficient and the depressed bone must be raised. Hartigan believes that many still-births are due to this same occipital pressure. He calculates that 25,000 children die annually in the United States from this disease, and he believes that many cases might be saved by manipulation of the cranial bones so as to relieve the cerebral pressure, though he admits that it is often exceedingly difficult to prevent the bones from slipping back into their original position and thus causing a recurrence of the symptoms.

— At the monthly meeting of the New York Medico-Legal Society, held April 9th, a paper was read by Dr. J. G. Johnson, of Brooklyn, on Poisoning by Canned Fruits and Meats. Representatives of the canned goods manufacturers and editors of several of the trade newspapers were present, and refutations of some of the statements in the paper were made by these.

— A case of sporadic cretinism, with appearance of myxœdema, was reported at a recent meeting of the Medical Society of London.

Reports of Societies.

BOSTON MEDICO-PSYCHOLOGICAL SOCIETY.

WALTER CHANNING, M. D., SECRETARY.

The Society held its twenty-first regular meeting at the house of Dr. J. H. Denny, February 7, 1884, Dr. Fisher occupying the chair.

Dr. Edward Cowles read the paper of the evening, entitled

A CASE OF HYSTEROID CONVULSIONS,

of which the following is an abstract: —

Mrs. A. B., twenty-seven years of age, admitted to the McLean Asylum in 1881. Has been under the care of Dr. Minot, of Boston, her family physician. Maternal uncle insane. Was of a nervous temperament when young, but fairly healthy. At the age of seventeen had a hysterical attack, followed by unconsciousness, owing to fright. During the following three or four years until her marriage had occasional attacks of unconsciousness which were called *petit mal*. These were apt to occur when her emotions were excited. She could ward off an attack for hours or a whole day when she knew one was impending, but it would usually occur sooner or later, as she yielded to its influence upon lying down at night, and it would be followed by sleep. The attacks were most apt to occur at a menstrual period, when she was nervous or restless; were milder between such periods. There was no struggling or movement in them.

Married in 1876 at the age of twenty-three; has three children. The last born six months before entrance to asylum. During pregnancies had added symptoms of pressure and pain in the head; then excitement sometimes followed the attack, making it necessary to hold her on the bed. The attacks occurred only at night, and only in presence of her husband, being successfully resisted at other times and concealed from other persons. Between pregnancies better than ever, attacks being infrequent and brief.

In third month of last pregnancy (ten months before admission) pressure and pain in head began, and seizures became more frequent, occurring several times daily, and sometimes lasting for an hour. Were more apt to occur if she was irritated or annoyed. These attacks were characterized by occasional rigidity of limbs and body, sudden starting movements and opisthotonos, and could often be arrested by suddenly seizing hold of her, blowing in her face, etc. She took, as she had before in her pregnancies, laudanum and stimulants, and added to them ether, chloroform, and chloral for the relief of pain and nervousness, but not habitually.

After last delivery had many seizures. Two weeks before admission pain in head and nausea. Accidentally fell down a flight of five steps backward, striking on back of head, which caused increased pain and nausea. Sometimes felt a desire to seize and hurt any one who came near her; also irresistibly drawn to throw herself out of a window, to get away from every one. The previous summer felt impelled to get out of window; the rays of the moon reflected from the water seemed to invite her to walk out upon them. The asylum gave her a sense of security and a feeling that she could do nothing harmful. Once had a suicidal desire to use a penknife, fearing she might be pregnant.

The patient is of unusual refinement and intelli-

gence, a good musician, of amiable disposition, and very fond of her children. Has suffered mental strain from various causes.

Menstruating when admitted to the asylum; was quite rational, and not much excited; in fair physical condition. Menstruation continued for seven days; had several brief periods of unconsciousness. Pulse 70, not perceptibly altered. Was given chloral, bromide of potash, elixir valerianate of ammonia. Slept fairly, though restless at night, with pain in head and apparent fright.

After menstruation ceased was better for a while, though nights were still poor. Several times on point of becoming unconscious, but warded it off by effort. At this time she was given nitrite of amyl to inhale, which put her to sleep and overcame the ill feeling or nervousness.

Two weeks after admission a seizure occurred as a result of something unpleasant said to her; appeared unconscious; lay in bed with eyes wide open, fixed, pupils dilated; very slight movement on touching conjunctivæ. Pulse 124. Under influence of nitrite amyl came to herself in an hour, after a series of partial relapses and actions of a purposive character. During the following month a similar condition was produced experimentally by causing her to look fixedly at a piece of paper held before and above her eyes.

During second menstruation attacks frequent and mild. A month later several severer attacks immediately before menstruation. In this and subsequent attacks would sit up in bed; jump off from it; dance about; whisper; laugh hysterically, etc.

After a few months, being somewhat better, went away for a visit, during which seizures returned with melancholia, suicidal propensity, etc., and she nearly threw herself from a fourth-story window, and was returned to the asylum after five months' absence.

During the following six months attacks occurred at frequent intervals, being of about the nature of those described above, a constantly recurring symptom being pain in left iliac region. About a year after first admission to the asylum was better than for two years, even going through menstruation once or twice without an attack; attained a greater weight than ever before. She soon began again, however, to have the attacks, and they became worse than before, and were brought on by lesser causes. In the autumn had lost much flesh and was unable to sit up without vertigo and nausea. She had hallucinations of sight, which continued for some months.

As a summary of the events of three years, in brief it may be said: There was improvement for two months; then development of disease outside of the asylum for five months. Then improvement for nine months followed by nine months of development of more serious symptoms than ever, with complication of painful inflammation of ears, requiring continuous use of morphia, hallucinations, delusions, danger of death by exhaustion, and general and painful cutaneous hyperæsthesia, etc. Again, during nine months to the end of 1883, gradual and remarkable improvement in general health and appearance, but with recurring severe attacks at menstrual periods, accompanied by the continuance of their most violent symptoms. Finally during the first month of the present year sudden relapse with the development of a new and dangerous neurosis of the heart. In one attack death seemed imminent. These attacks recurred in February.

47

Conclusion. The earlier history of this case led to the diagnosis of *petit mal* with a hysterical element. Later this was necessarily modified. There is a dissimilarity from hystero-epilepsy as described by Charcot, Richet, and others. The attacks do not begin with a convulsive seizure closely resembling true epilepsy. There is not a general severe tonic spasm, though tonic rigidity may occur later. There is no deviation of the head, or clonic spasm succeeded by coma and stertor. In the second stage the semi-purposive acts do not resemble the violent coördinated spasm, bounding movements, etc., and the opisthotonos is mild and accompanied by only mild tonic rigidity. In the third stage, however, there are the mental and emotional disturbances, with manifestation of joy, anger, irritation, the stage of delirium, and finally there are at times the terrifying visions.

Comparing the symptoms of the case with Gower's table of diagnostic characters of epileptic and hysterical fits, the former bear out the diagnosis of hysteroid convulsions. The most important indications are that the attacks are influenced by the patient's psychical condition, — the initial pseudo-epileptic phenomena may occur repeatedly during the progress of the fit, showing that they are actually part of the hysteroid attack, — and the cessation of these recurrences when the fit is cut short by treatment. Charcot's crucial test, compression of the ovaries, was sometimes successful, but usually failed to arrest the attacks, as is common in this country and England. According to Charcot, also, it is significant that in the intervals between and in the midst of the attacks there is no evidence whatever of the mental impairment to be expected from so long and severe a manifestation of epileptic symptoms.

The attacks being regarded as hysteroid, and being so distinctly associated with the menstrual function, the question has arisen of the propriety of removing the ovaries and Fallopian tubes. In view of the increasing seriousness of the patient's condition, and the hope of ameliorating the symptoms attending menstruation, should ovariotomy be performed?

In the discussion which followed the reading of the paper of Dr. Cowles, Dr. Jelly said: I am very glad to hear Dr. Cowles's paper, as I saw the patient in consultation with Dr. Minot just before she was committed to the McLean Asylum.

She was in a feeble condition of health, had a child but a few months old, and had had several seizures resembling *petit mal* (from the description given, I did not see her in one). She had had one or more on the morning of the day on which I saw her. Following this she had given them much trouble by attempting to throw herself from the window with suicidal intent.

At the time of the interview she was quiet and ladylike, but a little confused. As she was having the premonitory symptoms of the approach of menstruation, it was decided to wait until it became established before sending her to the asylum, as it was hoped her fear of pregnancy might thereby be relieved. She became more excited in a few days, and the suicidal tendency continuing she was removed to the McLean. I made no positive diagnosis at the time. I have no doubt from Dr. Cowles's careful detail of the history of the case that he has arrived at the correct diagnosis.

It seems to me if the case were one of epilepsy there must have been by this time some weakening of the

intellect, and more effect would have been noticed from remedies which generally are given for the relief of epilepsy.

I saw the patient for a moment last fall during the comfortable period which Dr. Cowles described, and she then appeared very calm mentally.

I have no experience from which to give an opinion as to the advisability of ovariotomy.

DR. PAGE remarked that he was very much interested in the paper of Dr. Cowles, as it had a direct bearing in many of its features to a case now under his care at the Adams Nervine Asylum, wherein the symptoms exhibited were remarkable for their unusual combination. Before describing it, however, he would like to ask Dr. Cowles if he understood him to say that his patient had ever had catalepsy.

DR. COWLES replied that on a few of the occasions where the patient was unconscious the arms and hands may have been made to maintain the position in which they were placed, but the symptoms were not regarded as cataleptic.

DR. PAGE said that there could be no doubt of the correctness of Dr. Cowles's diagnosis, and that it was associated with a mental disease quite distinct from the hysteroid condition, and quite independent of it. The progressive character of the mental element did not, it seemed to him, augur well for recovery. While no one, of course, could definitely state what the result might be, with the association of symptoms as presented by Dr. Cowles, the duration of the case, together with the recurrence of the hysteroid attacks, without assignable cause, unless we accept intra-cranial trouble, not necessarily organic, and the progressive mental implication, he could not but feel that the outlook was extremely dubious. At least his own experience in similar cases had taught him not to entertain hopeful views of recovery. As to the propriety of oöphorectomy, his own knowledge of cases of the double operation he had been able to observe and the ill success attending it made him suspicious of the wisdom of the operation in this particular case. In those with whom he has present acquaintance essentially the same condition exists to-day as prior to the operation. One was followed by persistent vomiting and profound disturbance of assimilation for more than a year; two others have the same train of symptoms as before; and another remains unchanged except in the loss of her ovaries.

His own case was that of a young married woman, of fine physique, cultivated and intelligent, recently admitted to his care, who was now passing through a series of severe hystero-epileptic attacks varied with catalepsy and ecstasy, and associated with total bilateral loss of hearing and loss of speech. He had just left her this evening free from convulsive attacks, but, as a result of them, in great emotional distress because she had become *totally blind*, proof of which was seen by the fact that no reflex action of the eyelids could be superinduced by making sudden demonstration before the eyes, as in the act of striking, and only so by placing the finger on the corneæ. Both pupils were widely dilated. She has also complete hemi-anæsthesia of the right side, with anæsthesia of the parts immediately surrounding the left ear and mastoid. The application of the tuning-fork induces vibratory sounds, noticeable only in the left middle ear, not in the right. Her feet have been all day in a state of contracture, and are only temporarily relieved by the faradic current. Accompanying one of the severe tonic spasms, when the hands, tightly closed, were flexed on the fore-arm as much as were possible, and the face intensely congested, was internal strabismus. On relaxation of the spasm, however, the eyes resumed their normal axes. The case is also especially interesting because it is associated with the opium habit. It was stated, on admission, by the attending physician, that the daily consumption was from half a drachm to one drachm of Battley's solution. An attempt was therefore made, as a means for cure, to break up the habit by withdrawing it altogether. It was not then known that the patient had experienced other than a cataleptic attack about one year ago. The result was severe hystero-epilepsy. During an intermission between one of these convulsive attacks it was discovered that the daily consumption was six grains morphia. To control the spasms, and at the same time to avoid danger from too sudden omission of morphia, forty minims of Magéndie's solution were administered, and this is all she has taken within the last twelve hours, with the effect of controlling the convulsive movements; but, as before stated, the patient has become totally blind in addition to the loss of the special senses already mentioned. The case is also novel because of the limited means of communication with her. Before loss of sight it was by writing on a slate, now by means of the finger alphabet. The patient inherits a neurotic tendency from the father, and since marriage has been subjected to severe emotional strain. At no time, however, save when first clearing up from the last convulsive attack, when internal strabismus existed, has she exhibited any intellectual aberration. I would add, further, that this patient was seen by Dr. C. J. Blake last August, and at that time was having an eczematous trouble with both external auditory canals. The hearing was then absent, and instead of being anæsthetic, as at present, the parts about both ears were hyperæsthetic. Speech was then perfect. Dr. Blake found no disease of the middle ear, but a slight thickening of the tympanum of one ear, and a small calcareous deposit in that of the other. I believe he regarded the loss of hearing as purely hysterical. At all events it has now existed one year.

DR. DENNY said the fact that symptoms ascribed to partial epilepsy were exhibited several years ago, which have since periodically recurred, the habitual recourse to narcotics to relieve pain and spasm, and the continuance of maniacal delirium almost uninterruptedly for months during the period occupied by lactation in ordinary puerperal evolution are points related in the history of the case reported which would lead us to anticipate the development of masked forms of mental and nervous phenomena such as have been manifested. The symptoms consequently have some of the characteristics of epilepsy, ovarian neuralgia, hysteria, and insanity in varying degrees. If true epilepsy exists it would be unreasonable, in my opinion, to attempt to cure it by extirpation of the ovaries, which is in effect an operation on the peripheral nervous system, since epilepsy is essentially a disease of the central nervous system.

The following are some of the symptoms which have a strong likeness to epilepsy: —

The patient will endeavor to ward off an attack by various expedients whenever she feels a warning, aura-like, malaise. This resembles the efforts of epileptics to cut short an impending attack by ligation of a limb, for example, between the aura-sensation and the body.

In any form of hysteria the tendency would rather be to exaggerate than to avert a crisis.

The peculiar dreamy expression of the eyes accompanied by occasional waking-up looks are suggestive of epilepsy, as well as the seeking to avoid falling by lying down in a comfortable, safe place previous to attacks. Such expedients are familiar in epilepsia mitior, and in graver forms when there is a warning aura.

Again, the absence of hemianæsthesia on the side of the irritable ovary, or of any *marked* disturbance of *cutaneous* sensation, would counter-indicate the existence of hystero-epilepsy according to Charcot. If, however, it were certain that deep pressure over the irritable ovary would stop an attack, it would go far towards proving the existence of hystero-epilepsy, whatever anomaly there might be.

In event of the symptoms being those of hysteria in any of its hysteroid or hystero-epileptic forms, or of ovarian neuralgia associated with delirium, involving the sympathetic tracts of the ovarian tubes, that is, functional neuralgia, operative interference would be unjustifiable, as would be the extraction of a tooth for a trigeminal neuralgia, as Drs. Landau and Remak conclude[1] after ably commenting upon a case of their own operated on for hystero-epilepsy which was much exacerbated thereby.

They state that "the diagnosis of functional neuralgia excludes surgical interference not only in distinct forms of the same, but for hysteria, ovarial hyperæsthesia, etc., as has been attempted by ovariotomy. Rosenthal and Neftel have detailed only bad results from such operations."

Professor Tauffer, of Heidelberg, relates[2] a case operated on by himself for combined hysterical and mental symptoms which was succeeded by mania and not by recovery, while another case was followed by dementia, although he says "the operation seemed indicated to prevent this termination." Other cases related by him and by Professor Goodell,[3] of Philadelphia, who anticipates the time when both insane men and women will be operated upon by legal requirement, do not seem to me to justify the mutilation yet.

Dr. Fisher remarked that the evening was so far advanced that he would not discuss the paper, merely stating that as he has always regarded confirmed hysterical insanity, *however* originating, as a disorder of the brain and not of the ovaries, he could not advise Battey's operation except as an experiment, or a *dernier ressort* for the possible effect of the shock or moral influence, or the improved nutrition likely to follow it.

Dr. Cowles said that his narrative of the long series of attacks and varying conditions of the patient had evidently given a wrong impression as to the prominence of mental symptoms, the fact being that all through the history of the case there were clear intervals between attacks, and that the patient appeared sane and well mentally much the larger part of the time. The mental symptoms were distinctly associated with the attacks except on two or three occasions, as when there was a period of painful inflammation of the ears and great physical exhaustion. Even when last in the puerperal state, neither before nor after confinement was there a continuance of delirium, except for a few brief periods. It was associated with the attacks, between which were intervals of mental clearness. The recourse to narcotics could not be regarded as at any time amounting to a habit.

As regards the symptoms that simulate epilepsy, the condition that led to efforts to ward off attacks might exist from one to four days, and while it may be termed an aura-like malaise, it differs from that of epilepsy, and such conditions are common to hysteroid attacks. Seeking to avoid falling, by lying down in a comfortable place, is more common to hysteria than to epilepsy; and the dreamy expression of the eyes might recur many times before the attack is fully developed, and also during the attack, which Gowers thinks is diagnostic. It is most significant that the attacks can be warded off, sometimes altogether, and sometimes be long delayed by exertion, excitement, or by an effort of the will.

It should be stated that when the patient feels comfortable and well an attack, usually the precursor of a series, may be determined in two ways: By some emotional disturbance, or by the onset of pain in the left ovarian region, which once beginning from any cause, as during menstruation or from pressure, will continue and establish the initial condition of malaise. For many years the patient has been in the constant habit of making gentle pressure with the hand upon this region while going to sleep at night. The symptom of hemianæsthesia absent in this case as well as the effect of pressure on the ovaries is said by Gowers to be far less common than in France.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

C. B. NANCREDE, M. D., RECORDER.

Thursday evening, March 13th. The President, Dr. Tyson, in the chair.

Dr. J. H. Musser presented a series of specimens illustrative of Hepatic Pathology. The accompanying paper will be shortly published in another form.

Dr. C. B. Nancrede presented a penknife blade, with the portion of bone transfixed by it, removed from the cranium of a boy aged nineteen years, where it had remained undiscovered for over six weeks. Owing to later developments the history of this specimen is also, for the present, withheld from publication.

Thursday evening, March 27, 1884. Vice-President E. O. Shakespeare in the chair.

CASE OF EPITHELIOMA OF THE STOMACH AND COLON, PRESENTING SINGULAR DIFFICULTY OF DIAGNOSIS.

Presented by Dr. J. H. Packard.

Dr. Packard stated that this case was placed at his disposal for report by Dr. H. M. Fisher, in whose wards at the Episcopal Hospital the man had been.

Alex. R., aged forty-seven, single, was admitted July 9, 1883. He had for about four months been unable to follow his occupation, that of a wagon driver. No history of syphilis; none of his family are known to have had cancer. His first symptom was discomfort after eating; later he had loss of appetite and pain in the stomach. Two months afterward he felt a hard tender mass in his belly, on the right of the umbilicus.

On admission the tumor seemed about the size of an orange, and was found to be on the left of the umbilicus. It was not very painful, but annoyed him. He was much emaciated, and in a cachectic state; his bowels were obstinately confined. Under treatment his condition improved, and he gained notably in appetite and strength. Subsequently a change for the worse took place, the tumor became more painful, he lost flesh and strength, and his appetite failed. As the tumor seemed to be entirely movable, it was decided that an attempt should be made to relieve him of it, and he was transferred to the surgical ward, under Dr. Packard.

October 11, 1883, after consultation, an incision was made over the tumor, in a vertical direction, and the tissues carefully divided until the abdominal wall proper was reached, when it became clear that there was firm adhesion between this and the new growth for a space of several inches in every direction. The operation was therefore abandoned, and the wound closed. Healing took place by the first intention, and the man even thought himself to have been benefited, although this was clearly imagination on his part. Emaciation steadily increased, and toward the middle of November the stomach became unable to retain food. From this time the symptoms progressed until death occurred, December 29th.

Upon post-mortem examination, it was found that there was an epithelioma of the pylorus, which had become adherent to the transverse colon, and the disease propagated to that structure, a communication taking place between the two cavities. Subsequently, by a local peritonitis, the affected parts had contracted adhesions to the parietal peritonæum at the point to which they had been displaced. The mechanism of this displacement does not seem to clearly appear.

MALIGNANT DISEASE OF THE PERITONÆUM AND ABDOMINAL VISCERA.

Presented by DR. JOHN B. ROBERTS for DR. V. HORNET, with an abstract of the latter's notes.

The patient, a woman of about fifty-eight years, had, four years previous to death, an attack of what was supposed to be gastro-enteritis of malarial origin. From this she never perfectly rallied, but had four or five intestinal hæmorrhages, at varying intervals. The last one occurred a few weeks before death. Recently she rapidly lost strength and became emaciated. When seen by Dr. Hornet, some time in December, 1883, she had a large tympanitic abdomen, and complained of a sense of tension. Constipation, jaundice, flushed cheeks. Pulse 100 to 110; normal temperature and a tendency to nausea and dyspnœa were the chief symptoms.

Ten days before death the thermometer in the rectum marked 103° F.; but stood, says Dr. Hornet, below normal in the axilla and under the tongue. Small nodules could be felt through the belly wall, which was less tympanitic than formerly. Death occurred suddenly while at stool.

Autopsy showed nothing important in the chest. The omentum and mesentery were studded with multitudes of tumors varying in size from that of a currant to that of a hen's egg. These were of globular form, firm in consistence, and on section showed a central hæmorrhagic clot. The parietal peritonæum was studded with a few small ones, as was the surface of the liver. Dr. Hornet further says that he found in one part of the intestine an ulceration of the mucous membrane corresponding to an internal tumor, and a tumor on each side of the rectum, high up. In one place he found a cyst, with yellowish serous contents, on the surface of a tumor. Most of the nodules were of a pale pink color; one noticed, however, was nearly black. I present a portion of the intestine and mesentery, and a piece of the liver with one of the secondary growths there found.

MALIGNANT DISEASE OF THE TESTICLE TAPPED FOR HYDROCELE.

Presented by JOHN B. ROBERTS, M. D.

This case is clinically interesting because it resembled a hydrocele, and misled me as well as another surgeon who had previously seen it. When the man came to me I found a large, oval swelling of left side of scrotum, which he gave me to understand had existed for two years. The tumor for six or eight inches long in the vertical direction had a sharply defined upper limit, as does hydrocele of the vaginal tunic, and was indistinctly elastic as is a tense hydrocele. The veins on the surface, however, were well marked, and it looked, at the lower part, a little as if the subcutaneous tissue was about to suppurate. It was this which gave rise to the pain that induced him to seek medical advice at this time, for he has previously postponed having another surgeon draw off the yellow water which he had been told was in it. I did not try to transmit light through the supposed hydrocele because it is very often a fallacious test. At least absence of light transmission does not negative the existence of hydrocele. I accordingly thrust a trocar into it, and drew about six fluid ounces of pure coagulable blood through the canula. Reinserting the trocar I pushed it in various directions, but met only solid tissue and no blood except when it was pushed in the direction originally taken. Then blood flowed in a quite free stream. No marked reaction followed, but the pain and tendency to suppuration was removed.

Two weeks later I removed the mass by enucleation, and found the solid tumor here presented, which is the enlarged and infiltrated testicle. The patient now says that fifteen years ago, when about eighteen years old, the testicle or scrotum began to grow larger. He is rapidly convalescing.

RUPTURE OF ONE OF THE AORTIC VALVES DURING SEVERE MUSCULAR STRAIN.

F. L., aged forty, laborer, married, was admitted into the Episcopal Hospital under my care February 21, 1884. His family history was good, and his own health, previous to his present indisposition, excellent. He denied ever having had syphilis or rheumatism.

His work compelled him to handle very heavy casks, and he had the reputation among his fellow-workmen of being a particularly strong man, he being able to lift, unaided, 500 pounds. Three weeks before admission he was subjected to heavy strains in lifting, and although no history of sudden cardiac pain or palpitation could be elicited, he did admit feeling a sense of tightness across his chest and some dyspnœa after his day's work, These symptoms gradually increased, and cough accompanied by bronchitic expectoration soon made its appearance. On admission the patient presented all the appearances of a remarkably well developed and powerful man; he was suffering from great dyspnœa, which was much increased upon exertion. Percussion showed impaired resonance over both lungs posteriorily, which was not altered by change of posi-

tion, and auscultation revealed numerous moist râles. The apex beat of his heart, although perfectly regular in its rhythm, was extended in its area, and in the nipple line in the fourth left interspace. Auscultation revealed a loud, high-pitched musical murmur, systolic in time, with its point of greatest intensity over the upper part of the sternum; this was also audible over the whole chest. The peculiarity of this murmur was its decidedly vibratory character, like a torn sail flapping in the wind; the patient himself even noticed this.

With the diastole there was a second murmur of much lower pitch and not musical or vibratory in its nature. This had its point of greatest intensity over the aortic cartilage.

There was no apex murmur. Slight œdema of the legs and feet was present. The urine contained no albumen.

The patient was placed in bed, and given digitalis, while counter-irritation and dry cups were applied to his chest posteriorly. Under this treatment he rapidly improved, and was soon considered well enough to be about the ward, the dyspnœa only showing itself after any unusual motion or excitement. The murmurs remained in much the same condition as on admission, although the intensity of the musical murmur had lessened.

On March 20th, in the evening, after a day as well as usual, he was seized with a severe attack of dyspnœa, with congestion of the lungs. He was considerably relieved by the application of dry cups. The next morning it was noticed that the œdema of the legs had increased, the dyspnœa was still present to a slight degree, and the only change perceived in the cardiac signs was a lowering of the pitch of the musical murmur.

On the 22d the dyspnœa had increased again, and for the first time a low, long, apex systolic murmur was detected; this was conveyed plainly into the axillary line. The musical murmur was of still lower pitch than before, and at the aortic cartilage the murmurs were much more plainly of a see-saw character.

Irregularity of the heart's action occurred now for the first time. On the 23d the area of cardiac dullness was as follows: In the horizontal line, at height of nipple, the dullness began in the middle of the sternum, and extended to the left to a point half an inch beyond nipple. In the perpendicular line drawn midway between the sternum and left nipple the cardiac dullness began in the third interspace and extended downward till lost in dullness of left lobe of liver. The area of dullness was not triangular with the base downward. Impaired resonance was now present over the whole chest both anteriorly and posteriorly, and no cardiac sounds could be heard on account of the great stridor and the violent movements of the chest. The apex beat could not be detected for the same reason. After this the patient became more and more cyanotic and short of breath, and died on the same day, namely, March 23, 1884.

Autopsy. Each pleural cavity contained several ounces of serum. The pericardium contained about one and a half ounces of serum in which several shreds of lymph were discovered.

In both ventricles were large clots, partly chicken-fat, extending through the semi-lunar valves.

The weight of heart, after being emptied of clots and blood, was one pound ten ounces.

The walls of the left ventricle were enormously hypertrophied, measuring seven eighths of an inch at thickest part; the cavity appeared slightly distended, as did also the mitral orifice, which would allow the tips of three fingers to pass.

The right anterior leaflet of the aortic valves was torn at its posterior insertion into the aorta, thus leaving a free pointed end about three eighths of an inch long to float in the blood current.

The left anterior leaflet presented two fenestrations, the posterior one the smaller and near the insertion of valve in aorta at its upper margin, the anterior one the larger and situated some distance down from the free border of valve.

The aorta at its origin was atheromatous in places and slightly dilated, a patch existing at the point corresponding to the former insertion of the torn valve. The valves were normal except for slight thickening. The coronary arteries were not atheromatous.

Remarks. In this case the atheroma at the point of insertion of the torn valve must have been the cause of the rupture during a heavy strain; should a fenestration have existed near the point of insertion, as exists in the left anterior leaflet, this would be a further reason for the rupture occurring at this point.

Frequently repeated great bodily exertion was the probable cause of the atheroma, as the man was a moderate drinker and denied rheumatism and syphilis. A point of interest in the case was the peculiar character of the *systolic* aortic murmur, which was, as before mentioned, decidedly musical and vibratory.

As the patient did not suffer from sudden palpitation and dyspnœa at the probable time of the rupture, and as this murmur gradually diminished in pitch, while the regurgitant murmur became slightly more pronounced, it is probable that the tear at first was slight and gradually increased under the great strain thrown upon it, thus increasing the area of the loose edge to be thrown into vibration, necessarily lowering the note produced.

The systolic apex murmur heard one day before death was due to the occurrence of an incompetency of the mitral valves from over distention of this orifice.

NEW YORK ACADEMY OF MEDICINE.

THE REMOVAL OF THE AFTER-BIRTH.

At a stated meeting of the Academy held Thursday evening, April 3d, Dr. H. J. Garrigues read a paper in advocacy of the exclusive adoption of the Credé method in the delivery of the placenta after normal parturition. It was now thirty years, he said, since Credé had published his original communication on the subject, and since the date of this publication he had repeatedly reiterated his conviction of the correctness of his idea that the placenta should be removed, not by traction from below, but through the agency of pressure from above. Having described the method in detail Dr. Garrigues maintained that it was a mistake to practice compression on the fundus except during a regular contraction. At least three contractions were, as a rule, required for the expulsion of the after-birth, and more frequently it was not until the fourth contraction that it came away. Of late years some of the German authorities had claimed that the Credé method was objectionable on the ground that it was likely to result in retention of the membranes, but he contended that there was no foundation in fact for such an opinion.

During the last eight years Dr. Garrigues had used the method constantly in his private practice, and when he was appointed attending surgeon to the Maternity Hospital on Blackwell's Island he had introduced it into that institution. During the last two terms of his service there 408 confinements had been recorded. Two of these had been cases of abortion at the fifth and sixth months respectively, and in both there had been adherent placentæ, which he removed by means of the dull wire curette and forceps. Out of the 408 cases there were six of retained placenta, and six in which a portion of the membranes was retained, so that out of 400 cases the Credé method failed in six, or one and one half per cent. In four, however, there was the occurrence of true adhesion of the placenta, which he believed to be more rare than was generally supposed, most of the cases of retention being due, as he thought, to improper treatment. There were, therefore, in reality only two failures in 400 cases, or one half per cent., there being two cases in which there was simple retention without adhesion. In six cases (or one and one half per cent.) shreds of membranes of larger or smaller size were retained, but in only one of these was it necessary to introduce the hand into the uterus to accomplish their removal. Credé had said that he had never seen any bad effects from leaving such portions of membrane, and advised that they should be allowed to remain undisturbed in the uterus, but Dr. Garrigues strongly deprecated this course as liable to expose the patient to severe hæmorrhage and other dangers. Whenever the membranes could not be removed otherwise, the hand, disinfected with a solution of bichloride of mercury (1 to 2000), was to be carried up into the uterus, and the cavity afterwards thoroughly washed out with the same antiseptic solution.

The Credé method, Dr. Garrigues continued, was modeled strictly after the regular course of nature, and its action was simply to assist nature in completing the normal process of parturition. After the strong expulsive efforts of the uterus during the second stage of labor some atony of the organ was, as a rule, apt to result, and the manipulations comprised in the method had the effect of spurring it on to the still further action required. In the large majority of cases there was, therefore, a call for artificial aid at this stage of labor, and this, there could be no doubt, was better supplied by the method in question than any other plan of procedure. Having spoken of the action of the two sets of muscles entering into the structure and controlling the contraction and movements of the uterus he showed how, in the manipulations of Credé's method, the action of nature was assisted by the compression of the organ between the thumbs and fingers, and the pressure downwards and backwards, forcing it towards the hollow of the sacrum.

By shortening the third stage of labor the method tended to prevent post-partum hæmorrhage. In the 408 cases mentioned serious hæmorrhage occurred in only two, and in but two others was there the slightest loss of blood beyond the normal amount. In all these four cases, however, the hæmorrhage occurred before any attempt had been made at expression of the placenta, so that in not a single instance was there any hæmorrhage after the removal of the after-birth. When properly carried out, therefore, the Credé method was the best preventive of post-partum hæmorrhage. Inversion of the uterus, which was facilitated by traction, was also powerfully counteracted by it. In some instances the whole after-birth was expelled completely outside the genitals, and where this was not the case it was advised that the membranes should be twisted into a rope before their withdrawal. There was, as a rule, no necessity for the introduction of the fingers into the genital canal, and the avoidance of this constituted one of the points in the modern antiseptic treatment of midwifery cases. Dr. Garrigues said that in his own practice he delivered the child while the woman was lying on the left side, but after the second stage of labor was completed he had her turn upon the back as the most advantageous position for the satisfactory completion of the third stage.

In his last published communication Credé stated that in 2000 cases the average duration of the third stage was four and a half minutes. The average time in the 408 cases at the Maternity Hospital on Blackwell's Island was somewhat longer; but while in the lying-in hospitals in Europe the same medical attendant remained on duty for several years in succession, and thus had the opportunity of acquiring special skill in all obstetrical manœuvres, in the latter institution the resident accoucheurs were changed every two months. Still, in his opinion, Dr. Garrigues said, it was totally unimportant whether a few minutes more or less were consumed in the third stage, as long as the correct principles were carried out in the treatment of it.

In making a plea for the orginality of Credé in the method he had advanced (which, he said, had been impugned in certain quarters), Dr. Garrigues claimed that he was entitled to the credit of advancing uterine compression as a means for expelling the placenta because (1) he advised it in all cases; (2) he directed that the uterus should be firmly grasped on all sides; (3) that the whole organ should be pressed downward and backward in the direction of the pelvic axis; (4) that the cord or placenta should not be touched unless there was adherent placenta; and (5) that the fingers should not be introduced into the genital canal. The advantages which he claimed for the Credé method were: (1.) Its certainty. (2.) Its efficiency in exciting uterine contractions. (3.) The prevention of post-partum hæmorrhage. (4.) The prevention of hour-glass contraction of the uterus. (5.) The prevention of inversion of the uterus. (6.) The prevention of avulsion of the cord or uterus. (7.) The prevention of uterine inertia.

There was still another plan of procedure, sometimes called the Strasburg method, which consisted simply in the absence of any kind of interference whatever, and which was as yet but an experiment. In 100 cases reported in which it had been tried, the placenta came away within half an hour in twenty-four cases, within one hour in twenty cases, within two hours in twenty-five cases, within three hours in eleven cases, within four hours in nine cases, within five hours in five cases, within six hours in three cases, within eight hours in two cases, and within twelve hours in one case. In every case it was found that the fœtal surface of the placenta presented first. In two cases there was hour-glass contraction of the uterus, and in one case there was a decided putrid odor. Dr. Garrigues said that he failed to see a single advantage in this method, and that it was not even natural, since the recumbent posture, in which the women referred to were kept, was unfavorable to the spontaneous delivery of the placenta. Dr. Engelmann, in his comprehensive

paper on parturition among savage peoples, had stated that the placenta generally followed soon after the birth of the child. When the latter was delivered the woman was apt to change her position, and if the afterbirth did not readily come away massage was frequently resorted to. Dr. Sussdorf in his account of the labor of an elephant related that the mother, in order to facilitate the completion of the third stage, pressed her abdomen forcibly against the stake to which she was chained.

In the 408 cases at the Maternity Hospital there had been no instance of hour-glass contraction, and this accident, according to the statistics of the best authorities, was more liable to occur where no compression was made than where the Credé method was employed. It was hardly necessary to point out, Dr. Garrigues continued, that it was positively dangerous to allow a placenta to remain in the uterus till it became offensive. On the other hand, there was no necessity for undue haste in delivering the placenta, and all that the accoucheur was required to do was to abridge the third stage of labor in such a way as to keep the patient from danger.

DR. ALEXANDER HUNTER, in opening the discussion on the paper, spoke of the advisability of commencing the uterine compression just before the delivery of the child, and said, in the course of his remarks, that he believed that the uterus should always be allowed to expel the fœtus from itself, and from the vagina also, unless the fœtus were in danger of suffocation. By thus resorting to abdominal pressure early he thought the delivery of the placenta was much shortened, as well as the danger of post-partum hæmorrhage diminished.

DR. HADDEN spoke of the evil consequences that were liable to result from improper management of the third stage of labor, and of the coolness, judgment, and intelligence required in conducting it satisfactorily. During the last twenty-five years he said he had attended about twenty-three hundred cases of confinement, and had never lost sight of the importance of attending with special care to this part of labor, the neglect to do which, if it was not followed by any immediate bad results, might leave the patient a chronic invalid. In his last thousand cases he had had one fatal case of post-partum hæmorrhage, but the patient was the subject of *purpura hæmorrhagica*. For the expulsion of the placenta it had been his practice to depend partly on gentle traction and partly on abdominal pressure. He always took pains to see that the uturus was afterwards firmly contracted, presenting a distinctly globular outline, and was accustomed to watch the patient for at least an hour and a half after the completion of labor. In the only case in his experience in which there had been an attempt at inversion of the uterus the accident occurred before any effort whatever had been made to remove the placenta, and was due, apparently, to a relaxation of the circular muscular fibres while the longitudinal ones were in active contraction. The fundus, to which the placenta seemed to be attached, was thus forced down so that it could be felt through the os, while there was a cup-shaped depression in the top of the uterus as felt through the abdominal walls. Up to that time he had been inclined to believe that traction on the cord might possibly induce inversion of the uterus, but now he was somewhat skeptical on this point, and it seemed to him that the cases which had been reported as of this character were in reality due to the fact that the placenta was attached near the fundus (a comparatively rare condition), and the effort to expel it resulted in the inversion of the organ.

DR. MARY PUTNAM JACOBI remarked that the expulsion of the placenta was being prepared for all through the later weeks of utero-gestation by the formation of thromboses around its edges. Up to that time the uterine circulation was predominantly venous, but when the time approached when the uterus was expected to undergo the active contractile efforts which were necessary for the expulsion of its contents the circulation gradually became more and more of an arterial character, through the formation of these thromboses and the migration of leucocytes, which caused coagulation and tended to cut off the supply of venous blood. The stimulus required for exciting uterine contraction could be supplied alone by arterial blood, and hence it seemed probable that in those cases in which there was a failure to contract there was an abnormal continuation of the supply of venous blood. The Credé method had the direct effect of diminishing the amount of venous blood going to the uterus, thus continuing the process already begun in the ordinary course of nature, and she believed that it was the only plan of procedure to be thought of at the present day.

DR. MUNDÉ, who had arrived too late to hear the paper, made some general remarks on the Credé method, in which he went over much of the ground covered by Dr. Garrigues. In the course of them he remarked, however, that after expression had been made, and the reduced size and spherical form of the uterus, as felt through the abdominal walls, indicated that it had left the cavity of the organ, the placenta sometimes did not appear at the vulva. In such cases it was probably retained in the cervical cavity (the cervix being of exceptional length), and no amount of pressure on the fundus would cause its expulsion. Here slight traction on the cord, or, what was safer, the introduction of the fingers or hand into the vagina to get hold of the placenta, was advisable, and if the ordinary rules of cleanliness in obstetric practice were observed he did not believe that the slightest danger could result from this procedure. Where the placenta was retained simply by the firm contraction of the os, as sometimes occurred, he recommended that its relaxation should be secured by the administration of chloroform. In some cases the repeated compression of the uterus required by the Credé method gave the patient more pain than was at all desirable, and here he thought it well to follow this up with gentle traction on the cord. Dr. Mundé was strongly opposed to leaving the delivery of the placenta entirely to nature, and thought it simply criminal to allow it to remain too long in the uterus. At the same time he did not believe in expelling the placenta too rapidly, for the reason that it was liable to thus become stripped of a portion of the membranes, which would be retained in the uterus.

DR. ISAAC E. TAYLOR spoke of the effect of stimulation of the cervix by the touch of the hand in exciting, through reflex action, the fundus to contract and throw off the placenta. He believed in imitating the process of nature, and strongly deprecated too hasty interference in the removal of the after-birth, which, he claimed, should be left largely to nature, and ought ordinarily to occupy from twenty minutes to one hour or more. He was in the habit of taking hold of the cord but of making little or no traction, and he thought

that the delivery of the placenta could be facilitated by modification of the position of the patient according to the part of the uterine walls to which the uterus was attached.

Remarks were also made by DRS. FRUITNIGHT, RANSOM, and SELL.

DR. GARRIGUES, in closing the discussion, said he supposed that it was quite natural that the three methods of which he had spoken in the paper should each have its advocates to a certain extent, but he did not think that any one present would be willing to trust entirely to the do-nothing plan. All agreed that the delivery of the placenta was a strictly physiological process, and hence that all efforts to facilitate this should be in imitation of nature. Traction on the cord, however, did not seem to him a natural process, and in his paper he had endeavored to point out that the different manipulations comprised in Credé's method had the same effect in dislodging and expelling the after-birth that the unaided efforts of nature had in cases where she was capable of conducting the third stage of labor to a successful issue herself. He claimed, therefore, that in the vast majority of cases no traction whatever should be employed. He did not mean to say that inversion of the uterus was always due to this; but, although paralysis of the point of placental attachment, as in Dr. Hadden's case, was one of the recognized causes of inversion, he had no doubt that in a certain proportion of cases the accident was directly attributable to traction. As to facilitating the delivery of the placenta by changing the posture of the patient in accordance with the point of attachment, as suggested by Dr. Taylor, he could not understand how this could be determined without introducing the finger or hand into the uterus, and this he considered unjustifiable under ordinary circumstances. He quite agreed with Dr. Taylor as to the imprudence of too hasty interference in cases of retained placenta, and in his own practice he was accustomed to wait for at least an hour and a half before introducing the hand into the uterus. But, as he had said before, he did not think it right to wait until the placenta began to decompose.

Recent Literature.

Seventieth Annual Report of the Trustees of the Massachusetts General Hospital and McLean Asylum. 1883.

The Seventieth Annual Report of the Massachusetts General Hospital and McLean Asylum shows, like its predecessors, in a general way the excellent work which is being carried on year by year by these noble charities for the good of the community dependent upon them, and gives the details of the operations of the Hospital, the Asylum, and the Convalescent Home during the year 1883. The Treasurer's account makes a better showing than in the three previous years, the excess of expenses over income — which is charged to the general fund — having been only $10,085, instead of $29,860, which it had previously averaged. The receipts at the McLean Asylum exceeded the expenses by $4341.18, while the expenses at the hospital exceeded the receipts by $13,296.47, and at the Convalescent Home by $1130.17. The legacies and bequests received during the past year have been large, amounting to the handsome sum of $227,720, and the annual subscriptions for free beds were $10,600.

Important changes have occurred in the Corporation, in the Board of Trustees, and in the Board of Visiting Physicians. The Corporation lost its Vice-President, Mr. Nathaniel Thayer, who on many occasions had proved a most liberal benefactor of the institution. We have previously recorded the death of Dr. Calvin Ellis, and still another vacancy was created among the visiting physicians by the resignation of Dr. B. S. Shaw after a connection with the hospital in different capacities of twenty-five years, having been at one time its superintendent.

A new and commodious building for the accommodation of the Out-Patient Department has been erected during the year, and is now in full and satisfactory operation. Particular attention is called to the fact that the Convalescent Home at Belmont is designed not only for convalescents from this hospital, but also from other hospitals, private families, boarding houses, etc., and the trustees desire to have it availed of to its fullest capacity.

The Superintendent, Dr. Whittemore, reports that there were 165 patients in the General Hospital at the beginning of the year, and 2020 were admitted during the year, of which 1319 were surgical and only 701 medical patients, a disproportion justifying the reputation which the hospital is gradually acquiring of sacrificing medicine to surgery. Of the whole number of patients treated during the year 473 paid in full, 79 in part, and 1633 were free patients. Of the average number of these free patients, 138, 70 were Americans and 68 foreigners. The average time of the free patients was 4.80 weeks, of the paying patients 2.75 weeks. The greatest number of paying patients at any one time was 49; in private rooms, eight; the greatest number of free patients, 168; the greatest total, 189. The least number of paying patients at any one time was 15; in private rooms, three; the least free, 118; the least total, 143. The proportion of ward beds occupied by free patients was 77 per cent.; by paying patients, 23 per cent. About 13.7 of the paying patients occupied private rooms. The average number of patients was 168: males, 105.5; females 62.5. Sixteen per cent. of the free patients were female domestics; 29 per cent. were laborers; 15 per cent. were mechanics; and nine per cent. were minors. Proportion of deaths to whole number of results, 8.93 per cent. Number of patients received on account of accidents, 432.

The Superintendent of the McLean Asylum, Dr. Cowles, gives the following among other details of the operations of that institution. There were 167 patients in the Asylum at the beginning of the year, and 109 admissions during the year, two men being admitted twice. Of the 107 persons admitted, 67 were regarded as recent cases, and 40 as chronic, or as incurable at the time of admission.

Seventy-five persons, 34 men and 41 women, had never been in any hospital. Of the remaining 32 persons, 18, seven men and 11 women, were admitted for the second time; seven, five men and two women, for the third time; three, two men and one woman, for the fourth time.

Thirty-four cases, representing 33 persons, 10 men and 23 women, were admitted as voluntary patients upon their written applications. Two of the men were not insane: one, a case of the opium habit, was dis-

charged recovered; and the other, of alcoholism, was discharged improved. Of the remaining 31 persons, 25, five men and 20 women, were cases of melancholia: four, one man and three women, were cases of mania; and two men were cases of general paralysis. Of these voluntary patients three, one man and two women, were committed while still resident at the Asylum; and one woman, already referred to, was discharged, and afterwards returned under a commitment. Eleven of the 34 voluntary cases, two men and nine women, were discharged within the year, recovered; four more, two men and two women, as improved or much improved; and two men and one woman as not improved.

There were remaining in the Asylum, under the voluntary relation, 15 persons, three men and 12 women, who entered during the year. Eleven of these voluntary patients had formerly been inmates of the Asylum.

The average duration of illness, from the beginning of attack, of all cases recovered, was 13.39 months; and the average duration of their hospital residence was 8.32 months. The percentage of recoveries on admissions was 33.94. The number of recoveries was larger by eleven than in the previous year.

The presence in the house of voluntary cases in increasing numbers has a good effect, Dr. Cowles thinks, particularly upon new comers, who, influenced by example, become sooner wonted to their residence. Sometimes, on the other hand, the indecision of patients as to whether to remain or go away is not beneficial. Other advantages of the voluntary method are the increased care and attention it induces hospital people to give such patients to make them contented; the necessity under which it lays friends of explaining their reasons for advising hospital residence, and the encouragement to others needing treatment which the example affords.

Much benefit was derived from the occupation by suitable cases of a sea-shore cottage at Lynn during four months of the warm weather. The employment of women as nurses in the men's wards is reported as meeting with unqualified success, and it is hoped shortly to improve the nursing service by introducing the training school system, which we should trust would eventually be felt as a benefit outside the Asylum.

A Manual of Medical Jurisprudence, with Special Reference to Diseases and Injuries of the Nervous System. By Allan McLane Hamilton, M. D. Bermingham and Company. 1883.

Dr. Hamilton is promptly on hand again this year (though the title-page says 1883) with his "little book" of 380 pages. "Its scope is limited," he says, "for I have only considered those conditions of the nervous system which nowadays are so often the bases of litigation." In such cases he hopes it will prove useful as a guide, and also as a book of reference for lawyers and doctors.

This modest little preface rather disarms criticism, for if an author aims at little or nothing and achieves it, who can say that he is not successful. If, on the other hand, he offers to the world a perfect and complete treatise, as he says, which is found on examination to be little more than a barren waste of words, he lays himself open to criticism.

Dr. Hamilton fulfills the promise of his preface and makes even a better book than he would lead us to expect. There is a good deal of value in it and a large number of illustrative cases are given, both old and recent, which have never before been collected in book form, though mostly familiar to the alienist. These cases are interesting, some of them recorded in detail, and will prove of particular value to the lawyer who wishes to crowd the interstices of his elastic brain with numerous facts for the morrow's fray, in which he will give the spectator the impression that for years he has made a special study of insanity.

The first sixty pages of the book are called General Consideration. In a very brief manner the definition of insanity, its classification, its various forms, suicidal attempts, premeditation, post-mortem examinations, etc., are considered.

Chapter II. is on the Legal Relations of Insanity, and covers 110 pages. It begins with Legal Tests, and under the heading of the Border-land of Insanity considers the case of Guiteau in a manner intended to be full, but, according to our opinion, narrow and contracted. Dr. Hamilton disposes of Krafft-Ebing's well recognized forms of insanity of *primäre* and *originäre Verrücktheit* as too sentimental. Guiteau, he says, was a neurotic criminal, and under a better environment might have been a useful member of society! He finally rests satisfied that Guiteau was an eccentric criminal, trying by his actions during the trial to humbug experts and jury.

Dr. Hamilton's whole account of the Guiteau case is an unconvincing personal argument rather than a historical statement of the case, but we can easily pardon him in a matter like this, where arguments to make out the sanity of the subject will always be necessary.

The remainder of Chapter II. contains many suggestions as to the conduct of the insane and numerous cases, all of interest, more particularly to the uninitiated student.

Chapter III., on Hysteroid States and Feigned Diseases, covers fifty pages, and contains much of interest. Some of the subjects treated of may have escaped the notice of many observers.

Chapter IV. is on Epilepsy and rather brief.

Chapter V., on Alcoholism, is also rather short.

Chapter VI. is on Suicide, and the concluding chapters (VII. and VIII.), on Cranial and Spinal Injuries, cover eighty pages, and give a little of everything bearing on these injuries.

Altogether, he who wishes to run may read this book, even if the pace be a rapid one. Our legal brother especially will do well to add it to his library.

A Short Manual for Monthly Nurses. By C. J. Cullingworth, M. D. 16mo, 79 pages. Philadelphia: P. Blakiston, Son & Co., 1884.

This is a sensible and well written book for the instruction of monthly nurses. It does not aim at teaching them how to perform the duties of the medical attendant, but tells them how best to manage a case in his absence, and also gives good advice about sending for the physician in the various emergencies before and after labor. The book will be of no especial value to a training-school nurse; but it is to be commended to the untrained as a safe and reliable guide.

Medical and Surgical Journal.

THURSDAY, APRIL 17, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

"FURTHER LEGISLATION TO PREVENT THE ADULTERATION OF FOOD AND DRUGS."

As our readers are already aware, the prosecution by the Massachusetts Board of Health, Lunacy, and Charity of certain manufacturers for selling drugs, — such as laudanum and citrate of iron and quinine, — which fell much below the legal standard of purity, has given rise to an attempt originating, as is more than suspected, with the convicted firms to induce the State Legislature to so modify the existing law of 1882, under which the prosecutions were successfully conducted, as to render it practically inoperative.

Advantage was taken by a majority of the legislative Committee on Public Health of a petition "for further legislation to prevent the adulteration of food and drugs" to bring in a report not only full of misstatements but containing recommendations calculated to defeat the object sought by the petitioners. The names of the signers of this report would seem to indicate that they were actuated by a variety of motives, but we were sorry to see among them that of a senator, a member of the Massachusetts Medical Society, who, after the very full discussion of the subject in committee, seems strangely enough to have been but little impressed with the claims which the general public, the medical profession, and the better class of manufacturers and dispensers of drugs make for a stringent law based on a fixed standard.

The recommendations of this majority report may be briefly stated as a substitution of one of the Dispensatories for the Pharmacopœia as a standard, the insertion of the word "materially" after the word "differs" in the paragraph defining adulteration, and an opposition to an increase of the appropriation for enforcing the law. In other words, the majority reported in favor of a loose law and an insufficient appropriation for its enforcement, and this in answer to petitioners "for further legislation to prevent adulteration." With the misstatements contained in this majority report it is not worth while to waste our readers' time.

The minority simply reported in favor of increasing the appropriation for the prevention of adulteration from three to ten thousand dollars, two fifths of this amount to be annually expended for the enforcement of laws against the adulteration of milk, the number of prosecutions and an itemized account of expenditures to be reported annually to the Legislature.

The House of Representatives last week, after a spirited debate in which the majority report was supported by a manufacturer of vinegar essence, spruce beer, and other "notions," by the paid attorney of one of the convicted firms, a member of the House, and by an eclectic medical practitioner, adopted the bill reported by the minority by a vote of one hundred and six yeas to fifty-six nays. It is now expected when the subject comes up in the Senate that honest dealing and the demands of our fellow citizens for further protection against impure drugs and adulterated food will meet with the same sturdy recognition.

The wise result reached by the members of the House of Representatives was, unfortunately, modified by the adoption of an amendment to the Act of 1882, proposed by a representative of Boston, which, in our opinion, will be found both unwise and unnecessary; unwise in so far as it may encourage the sale by grocers and others of such an article as laudanum for general consumption, and open a door — however moderate its dimensions — for fraud; unnecessary in so far as its objects are provided for in the very next sentence of the act itself.

According to section three of the Act of 1882 a drug is declared to be adulterated "if, when sold under or by a name recognized in the United States Pharmacopœia, it differs from the standard of strength, quality, or purity laid down therein." The amendment adopted inserts after the word "therein" the following: "Unless the order calls for an article inferior to such standard, or unless such difference is made known to the purchaser at the time of such sale, or appears obviously by inspection of the article itself."

However little comfort this amendment offers manufacturers of inferior drugs, the objections to it are sufficiently obvious.

We offer our readers outside the State of Massachusetts no apology for treating so much in detail a matter which at first sight may seem to them of purely local interest and perhaps of limited consequence. In reality it is neither. There are few subjects of more importance to modern society than the maintenance of a high commercial and hygienic standard for articles used as food or drugs. The standards and the provisions for their protection adopted in Massachusetts by the Act of 1882 are based upon the recommendations of the National Board of Trade. The emphatic reassertion of its law in regard to these points by one State is a direct encouragement to others. The specious pretexts under cover of which the law is assaulted in Massachusetts, and the facts and arguments by which these are rebutted, will be or will have to be repeated wherever the question is again agitated.

Honest manufacturers, intelligent pharmacists, and dispensers of homœopathic medicines all united here in cordially supporting the law. The threats of its opponents, on the other hand, that the trade and enterprise of Massachusetts would be throttled by the enforcement of the law seemed to find little credence, and the application of vulgar epithets to honest State officials who were conscientiously and judiciously dia-

charging their duties under the law evidently produced a directly opposite effect to that intended.

We respectfully refer other legislative bodies engaged in protecting their constituents against adulterations of food and drugs to the debate in the Massachusetts Legislature. And members of Congress who are now discussing the propriety of appointing a committee to investigate adulteration from a national stand-point would do well to give it their attention.

THE EDINBURGH TERCENTENARY.

The tercentennial anniversary of the University of Edinburgh to be celebrated to-day is an occasion of great interest to all educated men the world over. It is said that among the distinguished men who have been summoned thither *honoris causa* are MM. Charcot and Chevreuil, who will receive the degree of Doctor of Laws. The names of some of our own countrymen who are to be similarly honored have already been given in the Journal. The chief educational institutions of the world are to be represented at the academic assembly to be held on this occasion. A number of our American colleges have been invited to send their delegates. The principal of the University, Sir Alexander Grant, has prepared a history which gives the story of the rise of the different departments of instruction, and of the great men who have from time to time graced the various professorial chairs. Among the natural sciences none has been more ably taught at Edinburgh than medicine. A part of the fame of this as a medical centre is doubtless due to the "extramural" instruction there given, that is, by physicians not officially connected with the University but fitting young men for their diploma examinations. But how great is the debt of the profession to many of the renowned and revered men whose names stand on its professorial roll! Truly *exegeunt monumentum perennius ære.*

Some entertaining stories are told about the elder professors of medicine in this University. Among them was Charles Bell, who it is said once visited the class-room of Roux in Paris. Roux omitted his lecture and dismissed the class, saying, "Sufficient, gentlemen; you have seen Charles Bell." Sir James Y. Simpson's boldness in introducing chloroform gave him a reputation as universal as it was deserved. A Scotchman was presented at the Court of Denmark, when the king said, "You come from Edinburgh? Ah, Sir Simpson was of Edinburgh." Of Simpson himself it is said that he esteemed it a higher privilege to have delivered a woman without pain than to have been made physician to the queen.

Of the contemporaneous teachers at this seat of learning, and of the many men who in other departments than medicine have lent it renown, we cannot speak in detail. That there is no falling off in the quality of the instruction is shown not only by the fact that it is to-day the largest university in the world, but by what is more valuable than any numerical test, its reciprocal action on the mental status of the Scotch people, and by the lofty position which Edinburgh has so long held as an intellectual centre.

May the beneficent influence of this seat of sound learning in medicine and in art continue to grow during another three hundred years!

MEDICAL NOTES.

— The friends of Dr. Whittemore, the Superintendent of the Massachusetts General Hospital, will learn with regret that the indisposition from which he has been suffering for the past few months has necessitated the amputation of the right hand and a portion of the left. We understand that since the operation Dr. Whittemore has been relieved in great measure of the pain which had formerly been so severe, and is in a comfortable and satisfactory condition.

— A French lady is in the courts with two bills whose coincidence in point of time is rather aggravating to her. One is of 2000 francs from a dentist for making a false uvula, to obviate a somewhat nasal tone resulting from the amputation of the natural uvula, which she had procured. The artificial organ caused such interference with appetite, digestion, and speech that medical attendance was necessary, with the result of the second bill of 4500 francs. The dentist's bill was reduced by the court to 600 francs.

— A correspondent of the *New York Medical Journal* relates a case of the morphia habit where the victim took the remarkable dose of a drachm of morphia crystals at night and twenty-five grains in the morning daily for nine days. The reporting physician himself injected twenty-five grains at once, each of three successive evenings.

— Last month a serious case of poisoning, though fortunately not fatal in any of the patients, occurred in Scotland among the boys of the training ship Cumberland. The boys had been sent out for their usual morning exercise, and began gathering roots and herbs which were strewn along the shore. One of them, believing the herb to be harmless, commenced eating it, and his companions followed his example. Shortly afterwards ten of their number complained of sickness, and before they could return to the ship three of them fell into a kind of stupor, and lay helpless in the road. They were carried into a neighbor's house, where some warm milk was procured, but the lads gradually grew worse, as did also several others. Four of their number were conveyed to an infirmary in the neighborhood, where everything was done to produce nausea and to prevent them from falling into a stupor, but despite the efforts of the medical men they remained in an unconscious condition for upwards of five hours. The remaining six were taken on board the ship, where they were duly tended, but in the course of the afternoon it was found necessary to send one of them ashore to the infirmary. These five were in a critical condition for some time, one of the cases being almost hopeless; but all finally recovered. The herb which did the mischief was discovered to be of the hemlock class and of exceedingly virulent action.

— Dr. Saint-Martin (*Revue Médicale*, March 15th), in an inaugural thesis collects a few of the rare instances of rupture of the tunica vaginalis in hydrocele. The individual who has a voluminous hydrocele suddenly feels a keen pain in the scrotum, and on examination finds that the previously circumscribed tumor has disappeared, giving place to a general infiltration of the subcutaneous cellular tissue. In one case referred to, the scrotum, penis, and skin of the abdomen were enormously distended, as if by infiltrated urine. In such extreme cases there is danger of inflammatory complications; but ordinarily the fluid is absorbed and the rupture is an accident of slight importance. Occasionally, however, it gives rise to parietal hæmatocele. Usually the vaginal wound heals and the hydrocele is reproduced, suppuration with adhesions of the sac being rare.

— In one of the recent discussions on the cholera question before the Epidemiological Society of London a somewhat striking illustration of one mode in which cholera is propagated was furnished by Sir William Smart, K. C. B., R. N., who told how the French troops at Varna returned from a march into the Dobrudsha smitten with cholera, and encamped on a plateau, through which ran a stream, from the mouth of which the English admiral's ship and others obtained their water, while higher up the French soldiers were washing their soiled clothes. The flag-ship lost 140 men, but Sir William's, which had brought a supply of pure water from Corfu, remained perfectly healthy except once, when moored near the shore while the wind was blowing strong from the French camp a single case occurred. At his suggestion the captain took her straight out to sea, and no other case appeared on board.

NEW YORK.

— At a special meeting of the County Medical Society held April 7th Dr. David Webster, chairman of the Committee on the Collective Investigation of Disease, read the report of the Committee on Intestinal Obstruction, founded on the replies of members to whom blanks on the subject had been sent. Records, more or less complete, were received of fifty-one cases, in forty-one of which there was total and in four incomplete obstruction of the bowels. In twenty-four cases there was no stercoraceous vomiting, and in three no obstinate constipation, while in one there was no vomiting, though nausea was present. Twenty-one cases, or over forty-one per cent., recovered. Out of nine cases in which the abdomen was opened, and peritoneal bands divided, there were two good recoveries, while in a third case that might have recovered the fatal result seemed purely attributable to imprudence. In sixteen cases the causes of the obstruction were ascertained by operation or post-mortem examination, and were as follows: Peritoneal adhesions in eleven cases; twists in the intestine in two cases; stricture in one case; invagination in one case; and impacted fæces in one case. Dr. Webster then proceeded to read the reports of the fifty-one cases in detail, but before the reading was completed it was decided, on motion of Dr. H. G. Piffard, that the entire report of the committee should be entered upon the minutes and printed, and that discussion of the subject should be postponed until after printed copies had been sent to the members.

— Dr. Piffard then called up the subject of a bill, now pending in the Legislature, to incorporate a college of midwifery in the city of New York (a different one from the proposed bill in regard to which action was taken at the last meeting of the Society), and, on motion of Dr. A. W. Warden, the following preamble and resolutions were adopted: —

Whereas, An effort is being made to incorporate, by act of Legislature, a private institution under the name and title of the College of Midwifery of the City of New York, asking that such proposed institution have the right to confer the degree of graduate in midwifery, and that such diploma be a license to practice midwifery in the State of New York; and

Whereas, The bill incorporating such institution is defective in many important respects, and the objects sought by such bill are considered injurious to the interests of the State of New York and to the medical profession of the State; and

Whereas, No opportunity has been afforded to the medical profession of this State or to the Medical Society of the County of New York to be heard in regard to this measure; therefore

Resolved, That the Medical Society of the County of New York hereby petition that the Assembly of the State of New York defer action until such time as this Society can be heard in opposition to such measure.

Resolved, That a copy of this resolution, signed by the president and secretary of the Medical Society of the County of New York, be transmitted without delay to the Assembly of the State of New York.

On motion of Dr. Piffard it was decided that a committee should be appointed to go to Albany as soon as practicable to oppose the bill now before the Assembly, and a motion of Dr. Garrish having been carried to the effect that the committee should consist of two, and should be appointed by the chair, Dr. Alfred C. Post, acting president, appointed Drs. A. W. Warden and H. J. Garrigues as the committee.

— At a meeting of the Society of Medical Jurisprudence and State Medicine held Thursday evening April 10th, Dr. J. Henry Fruitnight read a paper on The Status of the Midwife, Legal and Professional, in the course of which he deprecated the large number of irresponsible and unfit women now engaged in the practice of midwifery, and contended that either midwives should be prohibited altogether from attending to obstetric cases or that they should be rendered better qualified for their duties and held responsible like physicians. The paper was discussed by Drs. H. J. Garrigues, A. W. Warden, J. C. Peters, A. Jacobi, R. Newman, E. C. Spitzka, and E. Harwood, and at the close of the discussion a resolution was adopted condemning the proposed incorporation by the Legislature of the college of midwifery, in regard to which action was taken at the meeting of the County Medical Society on the 7th of April.

— At a meeting of the Military Service Institution held at Governor's Island April 10th, Gen. Egbert Viele, Commissioner of the New York Park Department, read a paper on Camp and Garrison Sanitation. He began by showing from official statistics the enormous disproportion in a number of great wars between those killed in battle and those who died of disease. Thus, in the war between the United States and Mexico there were killed in battle 120 officers and 1429 soldiers, and died of disease 101 officers and 10,885 soldiers, to which if 9749, discharged for disability, were added, it would make an invalid loss of 20,634 out of the aggregate of 104,454 men engaged in the war; while during the late Civil War the Federal army lost 93,969 men who were killed in battle or died of wounds, and 210,400 who died of disease. Afterwards he spoke of the Walcheren expedition, sent out by the British Government in 1809 to take Antwerp, where more than 40,000 soldiers and a magnificently equipped fleet accomplished nothing on account of the disabling of the troops by disease, and in contrast to this described the building of forts on malarious islands at the mouth of the Savannah River during the late war, where the soldiers by the observance of strict sanitary discipline were enabled to withstand the injurious effects of their surroundings.

A critical examination into the barrack life of the British army made a few years ago, he went on to say, showed that over-crowding, bad ventilation, bad drainage, and bad water were the rule, and not the exception; but great improvements had been made in foreign camp sanitation, and he mentioned particularly the hygienic corps, thoroughly organized and educated in sanitary principles, which was one of the features of the military organization of Switzerland. He then proceeded to show how badly the United States army was quartered. Of all the 187 forts and barracks, he said, no two were alike in plan, profile, or perspective, and if there was any similarity, it was in the discomforts and inconveniences by which they were nearly all surrounded. Some of them had been constructed in such places and in such a manner that it would seem as if human ingenuity had been exercised to the utmost in order to achieve the climax of human stupidity, and the condition of the sea-board forts and harbor stations, he said, was particularly bad. In this connection he quoted the following from Surgeon Bill's report of experiments on atmospheric impurities of soldiers' quarters: "I made no examination of the barracks of Governor's Island, nor of the casemate quarters of the men. As well make an examination of a pig-stye. They disregard every modern notion of hygiene; they are dark, damp, cold, and may or may not contain excess of carbonic anhydride; probably they do not, and hence analytical results would merely mislead." Having described particularly the sanitary defects existing at Fort Adams, Newport, Fort McHenry, Baltimore, and Fort Hamilton, New York Harbor, he went on to say that the evils complained of were found in all the sea-board forts, and, what was worse, the most recent attempts which had been made at improved quarters had resulted in conspicuous failure; the combined result of cheapness, bad contractors, and of too little knowledge of the true principles involved in the construction on the part of those charged with the duty of their erection.

To remedy the errors of years, General Viele said in conclusion, would not be easy, but the principles of sanitation could at least be learned. A porous soil, with good natural drainage, should be selected for a camp. There should be good drinking water, which should never be polluted. The direction of the prevailing wind and sunshine should be considered. Shade trees were an essential element. The drainage should be made perfect. The disposal of refuse matter should be carefully arranged. No subject was less understood in garrisons than ventilation. Every man ought to have eight hundred cubic feet of space to himself, and this should have direct or indirect channels to the outer atmosphere. Disinfectants should be constantly used, and sulphate of iron was especially recommended for this purpose. A bad cook was declared to be the men's worst enemy, and the cooking should be daily inspected. Personal cleanliness should be systematically required, and all the conveniences for securing this provided. The paper was discussed by a number of army surgeons and other gentlemen present, and on motion of General Tower, who said that this important subject was now stirring up the whole medical corps of the army, it was voted that it should be published.

— The State Senate has passed the bill prohibiting the manufacture or sale of oleomargarine or other imitations of butter, and the Adirondack bill, entitled An Act to Create a Forest Commission for the State of New York, and making an Appropriation therefor, which provides for the appointment of three commissioners, with salaries of $2500, to lay out and locate the lands belonging to the State and protect them against trespassers, and for the appropriation of $15,000.

— The health authorities, in investigating the cause of a recent outbreak of typhus fever among the Polish Jews on the East Side, have found that the disease was imported. The first case reported was that of an immigrant child, who arrived here on the steamship Nebraska on the 22d of March and afterwards died of the fever, which she contracted on the vessel. Some of the other cases reported were among immigrants who arrived on the steamer Moravia on March 26th.

— In the death of Mrs. Oswald Ottendorfer, wife of the proprietor of the *New Yorker Staats Zeitung*, New York has lost one of its most liberal benefactresses. In addition to many other charities during her life she built the Isabella Home for Aged Women, at Astoria, in memory of a deceased daughter, at a cost of over $100,000, erected and furnished a wing of the German Hospital (the woman's pavilion) at a like cost, and expended over $150,000 for the German Dispensary Free Reading Rooms, now in course of construction. In her will, besides many other charitable bequests, she left $10,000 to the German Hospital and Dispensary of New York, and $5,000 to the German Hospital at Newark, New Jersey.

— The death of the oldest son of Mr. Joseph H. Choate, a member of the freshman class of Harvard College, who died at his father's residence in New York on the 5th of April, was due to apoplexy, although he was but nineteen years of age.

Miscellany.

MALARIA AND DIPHTHERIA IN CONNECTICUT.

THE secretary of the Board of Health reports for the month of February in Connecticut that the month does not present as good a record as it should for a short one. The total mortalities are too high, and the ratios are higher than those for the same month in previous years. The most noticeable event is the return of acute tertian ague. For some time past reports have been made of this recurrence, now here, now there, until it has extended over nearly all the region that has been invaded by malaria, where dumb ague and the like and the continued type of disease had been the rule. The last new start is reported from Middlesex County, from Durham, and adjacent towns, thus completing the whole area except here and there localities that have not yet showed the movement. It has been irregular both as to time and space, and at first suggests a renewed onslaught of malaria as it first appeared, but there is no increase in the periodic type, and, as a rule, after the appearance of quite a number of cases the frequency diminishes, and scattering cases continue to be encountered. As clearly defined cases of tertian ague had rarely been seen over a large area, where the decline of the periodic type and the decrease in malarial cases indicated an entire disappearance of the disease, the reappearance excites attention, and the developments will be closely watched to learn what the prospects are that the malarial type has become a permanent one. As typho-malaria fever still lingers in England we may expect the same result here, but whether acute ague is to be a regular affliction is another question.

The epidemic of diphtheria continued unabated during February. In Hartford the death-rate is even higher than in January, and the number from zymotic diseases and the infantile deaths are slightly increased over those of January. The total mortality since January, 1883, from croup and diphtheria is 295, a condition unprecedented in the sanitary history of the State.

DURATION OF THE MENSTRUAL HÆMORRHAGE IN RELATION TO THE DEVELOPMENT OF THE FŒTUS AT TERM, AND TO MULTIPLE PREGNANCY.

THE *London Medical Record* summarizes a paper by Cuzzi (*Rivista Clinica* and *Annali Univ. di Med.*, July, 1883), in which the author seeks to establish his conclusions on the basis of much statistical material collected in the clinics of Modena, Milan, and Turin. He was led to this research by the idea that by the amenorrhœa of pregnancy a so much greater quantity of maternal nourishment was retained for the benefit of the fœtus, as the sanguineous loss was greater in menstruation. Not being able to determine exactly the quantity lost at each period he took its duration as a guide which, considering the number of his observations, may be regarded as more or less equivalent. As to a longer duration of the menstrual hæmorrhage a corresponding ovarian activity can be supposed; so, also, the hypothesis may be justified of a more easy rupture of more ovisacs, and a greater probability of multiple pregnancy. From the analysis of very numerous observations Professor Cuzzi thinks himself justified in formulating the following conclusions: (1.) The weight and length of the fœtus at term are in direct relation with the number of days menstruation occupied. The longer the usual period of menstruation the heavier and larger the fœtus. (2.) There is a direct relation between multiple pregnancy and the duration of the menstrual period. That is, multiple pregnancy is most frequent in women in whom the period is long and the loss free.

INTERNATIONAL HEALTH EXHIBITION.

A SOMEWHAT novel feature in connection with the exhibition this year will be the establishment of a Library and Reading Room, a home for which the Executive Council have assigned in a large double room in the Albert Hall, overlooking the Conservatory. Steps have been taken to secure a representative collection of works on vital statistics, of reports and regulations relating to public health, of regulations with reference to injurious trades, and of works thereon, and of reports, statistics, and other works on the science of education. Foreign powers have been invited to lend their coöperation in this effort to create an international library of works of reference bearing on the two divisions of the Exhibition, and several responses have already been received. India and the Colonies have also been asked to contribute towards the same end. Publishers and authors have likewise been invited to forward copies of their works. In addition to the Library of Reference there will be a Reading Room, to which the current numbers of periodical publications of a sanitary or educational character will be admitted. All books and periodicals sent to the library and reading room will, under certain regulations, be arranged for the use of visitors, and not merely for exhibition. The books will be submitted to the jurors, and a full catalogue will be issued. All parcels for the Library and Reading Room should be addressed, carriage paid, to the Secretary of the Library Sub Committee, Royal Albert Hall, London, S. W.

April 2, 1884.

LIST OF CHANGES IN THE STATIONS OF MEDICAL OFFICERS UNITED STATES NAVY FOR THE TWO WEEKS ENDING APRIL 12, 1884.

WALES, P. S., medical director, granted one year's leave of absence from March 28th, with permission to leave United States.

BATES, N. L., medical inspector, ordered to Washington to attend sick officers.

BRADLEY, M., medical inspector, ordered to continue duty at League Island Navy Yard.

WHITAKER, H. W., assistant surgeon, ordered to Naval Rendezvous at Philadelphia, Pa.

GUNNELL, F. M., surgeon-general, appointed Chief of Bureau of Medicine and Surgery and Surgeon-General of the Navy, with the relative rank of commodore, from March 27th.

RUSH, C. W., passed assistant surgeon, ordered to Naval Academy.

MCMURTRIE, D., surgeon, detached from Naval Rendezvous, Philadelphia, and to await orders for duty at Navy Yard, Washington, D. C.

NELSON, H. C., medical inspector, ordered before Retiring Board.

GORGAS, A. C., medical director, to be medical director from 4th March on the active list.

BATTLE, S. W., passed assistant surgeon, ordered before Retiring Board.

WELLS, H. M., surgeon, detached from Naval Hospital, New York, to report at Bureau for special duty.

HIBBETT, C. T., passed assistant surgeon, placed on waiting orders.

STEWART, H., surgeon, placed on retired list from April 10th.

REPORTED MORTALITY FOR THE WEEK ENDING APRIL 5, 1884.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

[1] Of the above 139 deaths 41 were killed during the riot.

Deaths reported 2640 (no reports from Buffalo, Milwaukee, and Providence): under five years of age, 981: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 377, consumption 465, lung diseases 397, diphtheria and croup 111, scarlet fever 60, diarrhœal diseases 43, typhoid fever 34, measles 35, whooping-cough 21, erysipelas 17, puerperal fever 14, small-pox 16, malarial fevers 13, cerebro-spinal meningitis 10, typhus fever three. From *diarrhœal diseases*, Chicago 11, New York 10, Cincinnati six, Philadelphia and Malden three each, Boston, St. Louis, and District of Columbia two each, Brooklyn, Baltimore, New Orleans, Charleston, New Bedford, and Milford one each. From *measles*, New York 12, Baltimore 10, New Orleans seven, Chicago four, Brooklyn two. From *whooping-cough*, New York nine, Brooklyn, Boston, Baltimore, and Cincinnati two each, Chicago, New Orleans, Marblehead, and Lee one each. From *erysipelas* New York five, Boston three, Brooklyn and Chicago two each, Baltimore, St. Louis, Cincinnati, and Brooklyn one each. From *small-pox*, New Orleans 12, Cincinnati two, Pittsburg and Nashville one each. From *puerperal fever*, Boston four, Chicago three, Brooklyn and Nashville two each, Baltimore, St. Louis, Cincinnati, New Orleans, and Fitchburg one each. From *malarial fevers*, Brooklyn three, Chicago and Baltimore two each, New York, Philadelphia, St. Louis, Cincinnati, New Orleans, and Charleston one each. From *cerebro-spinal meningitis*, New York five, Philadelphia two, Chicago, Boston, and St. Louis one each. From *typhus fever*, New York three.

Six cases of small-pox were reported in St. Louis, Cincinnati one; scarlet fever 44, diphtheria 17, typhoid fever four, and measles one, in Boston.

In 96 cities and towns of Massachusetts, with an estimated population of 1,352,159 (estimated population of the State 1,955,104), the total death-rate for the week was 16.77 against 18.21 and 22.61 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending March 22d, the death-rate was 22.1. Deaths reported 3709: acute diseases of the respiratory organs (London) 373, whooping-cough 143, measles 141, scarlet fever 86, diarrhœa 42, fever 35, diphtheria 28, small-pox (Birmingham four, London, Liverpool, and Sunderland three each) 13. The death-rates ranged from 15.2 in Plymouth to 31.5 in Preston; Birkenhead 18.9; Leicester 19.6; Sunderland 19.9; London 20.6; Sheffield 21; Huddersfield 21.8; Birmingham 21.9; Liverpool 27; Manchester 27.9; Leeds 28.2. In Edinburgh 18.6; Glasgow 25.8; Dublin 27.5.

For the week ending March 22d, in the Swiss towns, there were 36 deaths from consumption, lung diseases 27, typhoid fever 35, diarrhœal diseases 24, whooping-cough seven, diphtheria and croup six, scarlet fever five, measles one. The death-rates were, at Geneva 40.8; Zurich 19.7; Basle 25.6; Berne 28.9.

The meteorological record for the week ending April 5th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps: —

Date. March–April, 1884.	Barometer. Daily Mean.	Thermometer. Daily Mean.	Thermometer. Maximum.	Thermometer. Minimum.	Relative Humidity. 7.23 A. M.	Relative Humidity. 3.23 P. M. OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM MARCH 29, 1884, TO APRIL 11, 1884.

WOODHULL, ALFRED A., major and surgeon. Granted leave of absence for twenty-two days, to take effect about April 6, 1884. Paragraph 13, S. O. 72, A. G. O., March 28, 1884.

WHITE, ROBERT H., captain and assistant surgeon. To be relieved from duty at U. S. Military Academy, West Point, N. Y., August 28, 1884. Paragraph 7, S. O. 74, A. G. O., March 31, 1884.

MEARNS, EDGAR A., first lieutenant and assistant surgeon. Assigned to duty at Fort Verde, A. T. Paragraph 1, S. O. 22, headquarters Department of Arizona, March 19, 1874.

SUTHERLAND, CHARLES, colonel and surgeon. To be relieved from duty in Division of the Pacific and to report to the commanding general, Division of the Atlantic, for duty as medical director of that Division and of the Department of the East. Paragraph 4, S. O. 78, A. G. O., April 4, 1884.

BAILY, ELISHA J., colonel and surgeon, ordered to report to the commanding general, Division of the Pacific, for duty as medical director of that division and of the Department of California. Paragraph 4, S. O. 78, A. G. O., April 4, 1884.

STERNBERG, GEORGE M., major and surgeon. Ordered to be relieved from duty in Department of California, and to report to commanding general, Department of the East, for assignment to duty.

MOSELEY, EDWARD B., captain and assistant surgeon. Ordered to be relieved from duty in Department of the East and to report to the commanding general, Department of the Columbia, for assignment to duty. Paragraph 4, S. O. 78, A. G. O., April 4, 1884.

SMITH, JOSEPH R., major and surgeon. Directed to represent the Medical Department of the Army at the annual meeting of the American Medical Association, to be held in Washington, D. C., on the 6th of May, 1884, and on the adjournment of the Association to return to his proper station (San Antonio, Texas). Paragraph 7, S. O. 81, A. G. O., April 8, 1884.

WILCOX, TIMOTHY E., captain and assistant surgeon. Ordered to be relieved from duty in Department of the Columbia and to report to the commanding general, Department of the East, for assignment to duty. Paragraph 4, S. O. 78, A. G. O., April 4, 1884.

OBITUARY.

DR. PLINY A. JEWETT, a prominent practitioner of New Haven, and well known as having been an expert witness in a number of important medico-legal cases, died April 10th in Providence. He went to Providence a week before to testify, as an expert, in a murder case, and was taken with pneumonia. He was a life director in the Connecticut General Hospital, and during the war was in charge of the military hospital in New Haven. He graduated from Trinity College in 1837, and was appointed Professor of Obstetrics in Yale College in 1856. He leaves two sons and one daughter.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The annual meeting of the Suffolk District Medical Society will be held on Saturday, April 26th, at 7.45 P. M. Dr. A. Day will present a paper entitled Popular Medical Delusions. Other papers will also be presented. Business: Election of officers. The following is the ticket reported by the nominating committee: *For President*, James C. White. *For Vice-President*, George B. Shattuck. *For Secretary*, C. M. Green. *For Treasurer*, E. M. Buckingham. *For Librarian*, B. J. Jeffries. *For Commissioner of Trials*, Charles W. Swan. *For District Nominating Committee*, George C. Shattuck. *For Committee of Supervision*, Benjamin S. Shaw, Samuel A. Green. *For Committee on Social Meetings*, Calvin Stevens, H. I. Bowditch, George W. Gay. *For Censors*, A. N. Blodgett, E. G. Cutler, T. M. Rotch, F. C. Shattuck, F. H. Williams. *For Councilors*, S. L. Abbot, James Ayer, H. H. A. Beach, H. J. Bigelow, C. J. Blake, J. G. Blake, H. I. Bowditch, S. Cabot, D. W. Cheever, Hall Curtis, H. Derby, O. W. Doe, F. W. Draper, Thomas Dwight, W. H. Thorndike, R. H. Fitz, C. F. Folsom, J. O. Green, S. A. Green, F. B. Greenough, W. H. H. Hastings, J. R. Draper, R. M. Hodges, C. D. Homans, John Homans, W. Ingalls, B. J. Jeffries, F. I. Knight, S. W. Langmaid, G. H. Lyman, F. Minot, C. B. Porter, John P. Reynolds, W. L. Richardson, G. C. Shattuck, B. S. Shaw, A. D. Sinclair, D. H. Storer, A. M. Sumner, C. W. Swan, G. G. Tarbell, O. F. Wadsworth, J. C. Warren, Thomas Waterman, James C. White, E. N. Whittier, W. G. Wheeler, H. W. Williams. Supper at the usual hour.

H. C. HAVEN, *Secretary*.

THE AMERICAN MEDICAL ASSOCIATION. SECTION OF PRACTICE OF MEDICINE. — The chairman, Dr. John V. Shoemaker, of Philadelphia, Penn., submits the official programme for the meetings of the Section of Practice of Medicine, to be held in Washington, D. C., Tuesday, Wednesday, and Thursday afternoons, May 6, 7, and 8, 1884. The following special subjects have been promised, and those who are announced to enter into the discussions have accepted and will be present: (1.) Discussion on A Contribution to the Clinical Study of Epilepsy, will be opened by Prof. William Pepper, of Pennsylvania. (2.) A discussion on the Clinical Study of the Heart Sounds, will be opened by Prof. Austin Flint, Sr., of New York. (3.) A discussion on Tuberculosis, will be opened by Dr. Henry F. Formad, of Pennsylvania. No less than twenty-one papers on various medical subjects are also promised, and have been accepted.

BOOKS AND PAMPHLETS RECEIVED. — The Pathology, Diagnosis, and Treatment of Diseases of the Rectum and Anus. By Charles B. Kelsey, M. D., Surgeon to St. Paul's Infirmary for Diseases of the Rectum, etc. With two Chromo-Lithographs and nearly 100 Illustrations. New York: William Wood & Co. 1884.

Moral (Affective) Insanity, Psycho-Sensory Insanity. By C. H. Hughes, M. D., St. Louis. (Reprint.)

Shakspeare as a Physician. Comprising every Word which in any Way relates to Medicine, Surgery, or Obstetrics found in the Complete Works of that Writer, with Criticisms and Comparison of the Same with the Medical Thoughts of To-Day. By J. Portman Chesney, M. D. St. Louis: J. H. Chambers & Co. 1884.

Lectures.

CLINICAL LECTURE ON A CASE OF MYXŒDEMA.

BY ROBERT T. EDES, M. D.,
Visiting Physician Boston City Hospital.

A PATIENT was exhibited whose history, as elicited by a member of the class, with some assistance from the hospital books, was as follows: —

She is forty-five years old, and is still menstruating regularly. She has two children, the youngest being thirteen years old, and is a housekeeper of regular habits. She has had "neuralgia" for nine years. For the last two years she has had some indistinctness of vision, and also some swelling of the eyelids, two facts which she seems to consider (incorrectly) to be related to each other. She has also had some swelling of her hands and wrists, but says there has been none elsewhere. She complains of some prickling and numbness in her hands and feet, which are apt to be cold. According to her own statement she was formerly of a more lively disposition, and talked more rapidly than at present, though whether this change is greater than can be accounted for by the sobering influence of years is not apparent, and no friends have given us any history of her former characteristics.

She has suffered from frequent headaches. There is no cough, but a certain amount of dyspnœa on exertion. Her appetite is only moderate, her digestion not very good, and a moderate degree of constipation is present.

Upon examination she is seen to be a woman rather inclined to stoutness, with a rosy complexion, and a peculiar physiognomy. The whole face appears somewhat swollen, including the lips, which gives a heavy and mask-like expression to the lower part of the countenance. The cheeks are quite red, but the eyelids and forehead are rather brown and dusky. The hair is quite abundant, and very dark brown, slightly streaked with gray. Her hands, small, and naturally well shaped, are a little swollen, so that her wedding ring has not been removable for a long time, though she says she can turn it round. The ends of the fingers are *not* clubbed. The skin of the hands is dry and rough. The legs, which she says are not swollen, are very slightly so, and can be slightly pitted by firm pressure. The subcutaneous œdema of the eyelids and hands is not easily to be driven out by pressure as is the case with an ordinary serous anasarca. The thyroid gland, so far as it can be distinguished from the adipose tissue of the neck, is neither absent nor enlarged. Her speech is slow and deliberate, but perfectly distinct and well articulated. Her mind seems perfectly clear, and there is no apparent delay of comprehension or answer. The hearing is considerably diminished, as she hears the watch only at ten inches. Dr. Green finds no advanced aural change, but a little opacity of the lower part of the drum membrane.

It was not unnaturally thought, at first sight, that these symptoms pointed to a chronic nephritis, but a further study of the case renders this diagnosis improbable, that is, so far as either of the ordinary forms is concerned, for in the first place the urine is not that of *parenchymatous* nephritis, as it is found of about normal specific gravity, and not deficient in quantity (from about thirty ounces or a litre to double this quantity), while the albumen is either none at all (hospital) or a very slight trace (Dr. Wood), and there are a *few* transparent and granular casts of medium diameter. If this were the urine of *interstitial* nephritis, which, so far as albumen and casts are concerned, it might well be, its quantity should be much larger. In this case, too, if it had gone on long enough to give rise to dropsy, we should have a right to expect cardio-vascular changes consisting in hypertrophy of the heart and the pulse of high tension, neither of which is present, as may be shown by a physical examination of the thorax and the sphygmographic tracing which has been taken. The dimness of vision, already spoken of, does *not* depend, as we are informed by Dr. Wadsworth, upon albuminuric retinitis, of which she shows no trace, so that if this is a case of chronic nephritis it is a very unusual one. But it is no more than fair to say that it has been claimed by one physician who has given special attention to renal diseases (Dr. Mahomed) that cases of the kind which we shall consider this to be are neither more nor less than exceedingly chronic examples of Bright's disease. Most authorities, however, and it seems to me correctly, consider them as forming a very distinct group which has little to do, at least in the early stages, with nephritis, although changes in the kidneys, in common with other organs, have been found after death. They have received the name of myxœdema (Μυξα, mucus) from the peculiar character of the œdema, which does not consist, like ordinary œdema, in the accumulation of serum in the subcutaneous and submucous cellular tissue, but, in places at least, of a firmer substance, which is less easily displaced by pressure, and contains mucin and an abnormal number of swollen nuclei.

It will be admitted, I think, that the case before us, if her most prominent symptoms be compared with the descriptions given by many observers, is fairly to be classified under this head, but other conditions to which much importance has been attached, and which, indeed, lend a considerable part of the interest which is now felt in this curious affection, are but slightly developed. It is evident that our patient is not an advanced case. The general state of her nutrition is not so far "below par" as in most of the cases recorded. Thus the temperature is not below the normal standard, as it has been usually found. As to the amount of urea excreted, one quantitative analysis has given about twenty-five grammes per diem. She has not the œdema of the palate, glottis, and pharynx which cause the nasal voice and sometimes difficult respiration. Her hair has not suffered.

It is, however, in regard to the nervous symptoms, so pronounced in many cases, that we notice the most marked difference from the type. To represent these she has only the numb feelings in the hands and feet, and the slight sluggishness of manner. Of the incoordination, which has caused, at times, confusion between this disease and locomotor ataxy, or the condition spoken of as cretinism, she has hardly a trace. Whether these are to come or not, time alone can show, but in consideration of the short time during which this distinct type of disease has been recognized, and the somewhat limited statistics in our possession, we may consider it at least possible that there may be cases in which these are fortunately absent or long delayed.

In view of the infrequency with which these cases have been met with it was thought that an examination of the condition of the blood might prove interesting, but it showed no deviation from the normal, the

amount of hæmoglobin as shown by Gower's color estimate being equal to that of a healthy person, and the count of the blood corpuscles being 4,625,000, the corpuscles not being deformed, and there being no excess of leucocytes or microcytes. It is seen that at present there is no anæmia.

Two other cases were briefly described by the instructor for purposes of comparison. The first of these, presenting more of the classical features and evidently more advanced, came under observation thirteen or fourteen years ago. I used to meet in the street a rather large woman, walking slowly and much wrapped up, with a pale, swollen face, whom I supposed to be suffering from chronic Bright's disease or the most extreme anæmia, and mentally made a most unfavorable prognosis, expecting her to die within a year or two at the furthest. This was before I knew anything about her professionally or about myxœdema either.

Some time, I think some years, afterward I found a condition similar to that of our patient here but much more extreme, especially as regards loss of strength and the degree of anæmia. Her illness dates back to the cessation of menstruation.

There was great swelling of the whole face, the lower eyelids hung down in great bags, and the hands were of the most ponderous proportions, but neither white and shiny like those of renal dropsy nor cold and purple like those of impeded circulation.

Her voice was a little hoarse, and together with her general manner exceedingly slow and deliberate, though how great the change may have been from her former condition I cannot say, as I had not known her in health. Her appearance was noticeable from the amount of wraps she habitually used even in warm weather. She has from time to time had shooting pains in the limbs and stiffness in using them. She has suffered a large part of the time from chronic diarrhœa with much pain, for which various drugs have given only temporary relief, the most trustworthy being opium, which unfortunately she does not bear very well.

Her urine was found at various times of the specific gravity 1.016 to 1.034, and not notably changed in quantity. I was greatly surprised never to find in the several examinations I made any albumen, and on the only occasion where I find casts distinctly spoken of in my notes (though I have no doubt I examined several times) their presence is denied.

Her blood count was 3,320,000.

A noticeable feature in her case was the entire loss of her hair, which has, however, since been replaced by a new growth of soft brown hair several inches long all over her head. She remains in essentially the same condition, though having lost in strength, and is a striking instance of the chronicity of the disease.

Another case, which in some respects was the most marked of the three, and presented special points of interest, was seen about two years ago with Dr. West, of Roxbury, who will soon report it in detail, together with the autopsy.

In this case the physiognomy was similar to that of our patient, but the voice, probably owing to œdema of the palate, pharynx, and glottis, was husky and nasal. She died suddenly after going to bed in no worse condition than usual, attention being called to her by the cessation of the snoring. This result is to be looked upon as an accident to which such patients are liable rather than the natural or usual termination of the disease.

The morbid appearances in this case were largely negative, but showed in some certain localities the presence of a peculiar form of œdema. I understand they are to be reported in detail in connection with the clinical history.

The pathological appearances found in this affection have already been spoken of in a general way, and many of the symptoms, especially the nervous ones, have been accounted for, with some probability, by supposing that the general deposit of mucous tissue so "pads" the ends of the sensitive nerves and perhaps also the nervous centres as to destroy the delicacy of their function. This is, however, as yet to a considerable extent theoretical, and we have to wait for further observations in this direction.

There is no reason to suppose that the prognosis of the case before us differs in any essential respect from that which is usual. It is stated that the condition generally grows worse, that marked anæmia and renal disease accompanied by the ordinary form of dropsy are likely to supervene; the nervous symptoms become aggravated, the patient gradually getting into a condition described as closely resembling cretinism.

Quite recently it has been found that patients whose thyroid glands have been completely removed present after a time symptoms almost identical with those of advanced myxœdema.

There have been exceptions enough to this unfavorable prognosis to give a certain amount of encouragement that a cure may not always be impossible, or that at any rate symptoms may be mitigated and life prolonged even beyond the usual very chronic course. Curiously enough it has happened that in some cases when *ordinary* dropsy comes on as a consequence of renal disease supervening on the condition we are now discussing the *myx*-œdema has disappeared.

One case is reported where abdominal dropsy occurring in a man affected with myxœdema grew sufficiently severe to demand tapping, which having been done both ascites and myxœdema disappeared. In another case pregnancy and childbirth, which was accomplished with some difficulty, put an end to the morbid condition. Other cases of recovery have been spoken of as not due to any specific treatment. Where, however, the progress is steadily toward the worse it is often extremely slow. In the second case spoken of in this lecture the disease has been going on probably for at least fourteen or fifteen years, with no immediate prospect of a fatal termination, though there is a very decided loss of strength.

No treatment so far proposed has been attended with invariable or even very marked success. Favorable results have been claimed for strychnine, and quite recently for jaborandi in not too large doses but continued for a long time. Hot-air baths may also be of service, the action on the skin of the last two remedies being obviously very similar.

In our case nothing very active has yet been done. It is well, in hospital practice at least, when the case is not urgent to wait a little to see what change and rest will do; in this way many mistakes as to the effects of remedies may be avoided. She has had iron and quinine and the faradic current to the hands, which has relieved some of the uncomfortable sensations. She expresses herself as much better, and there is certainly less swelling than when she entered. By and by perhaps jaborandi may be used.[1]

[1] She has since left the hospital.

Original Articles.

THREE CASES ILLUSTRATING SOME POINTS IN THE PATHOLOGY OF CERTAIN INJURIES OF THE SHOULDER-JOINT.[1]

BY C. B. NANCREDE, M. D.,

Surgeon to the Episcopal Hospital, and to St. Christopher's Hospital for Children.

A few preliminary anatomical points must be passed in review for the ready comprehension of my later remarks. The shoulder-joint differs in many important points from any other articulation of the body. A moment's reflection upon the almost unlimited range of movement which it enjoys will at once suggest that the ligaments of this articulation cannot be the means by which the joint surfaces are held in apposition; otherwise anything like freedom of movement would be impossible in a ball and socket joint where the socket is so shallow as in this articulation. What then does hold, firmly apposed, the articular surfaces? It must be something always tightly stretched, yet always capable of lengthening or rather always practically loose. Nothing but muscle could fulfill any such purpose. In truth, the muscles surrounding the joint are the most important ligaments the articulation possesses. When these are paralyzed, or in the cadaver, the head of the humerus readily falls away from the glenoid fossa. Bearing this fact in mind, you will clearly apprehend that the joint surfaces are kept pressed together solely by muscular tension. Again, the glenoid fossa, unlike the socket of any other important joint, *has no epiphysis*, which explains to a degree the fact that even in the young the head of the humerus may be so affected as to demand excision, while the glenoid process is either entirely or nearly healthy. Closely related with the scapulo-humeral joint, we find a number of bursæ, some of which commonly communicate with the joint, while others do not. To the former alone I shall devote my remarks. There is a large one between the acromial process and the coraco-acromial ligament upon the one hand, and the shoulder capsule upon the other. Two bursæ — the exact sites are unimportant for our present purposes — are situated between the subscapularis muscle and the capsule. An occasional one is placed between the infraspinatus muscle and the capsule, into which it often opens, as do the others just mentioned. Let an inflammation be set up in these sacs, and it certainly spreads to the joint itself, should communications exist, or nearly as surely by mere contiguity of tissue, if no opening between joint and bursæ is present. The articulation is securely covered in by the voluminous deltoid, so that any direct injury to the fibrous or synovial tissues of the joint is almost impossible from direct force, as a blow, although a twist *may* injure it, notwithstanding the latter is more apt to tear the bursal walls. The upper epiphyses of the humerus — of which there are three — coalesce at five years, but they leave a layer of epiphyseal cartilage between head and tuberosities and shaft, which in places either coincides with the capsular attachment or is actually within it. From these anatomical facts it must be clear that direct force, as a blow, can rarely injure the joint itself, but must either set up trouble in the surrounding bursæ or in the epiphyseal cartilage, or in both. Once again the interior of the joint, the muscles moving the joint, and the skin over their attachment are all supplied by the same nerve or nerves; so that let a joint injury start where it may, the articulating surfaces of the shoulder-joint are subjected to such an injurious degree of pressure from direct or reflex muscular contraction as is possible for no other articulation. The bearing of these anatomical facts upon prognosis and treatment need hardly be pointed out.

The first specimen I proposed showing was presented to the Society some years back, and my reason for again showing it is the sharply contrasted result presented by the second specimen which I shall exhibit.

On November 27, 1878, the Society had an opportunity of examining the first patient and the admirable results of the case. To those who were not present, or who have forgotten the details, I will briefly recapitulate the history of the case, with the treatment pursued: —

COMPOUND FRACTURE AT THE ANATOMICAL NECK OF THE HUMERUS.

The patient, J. M., aged fourteen years, fell, upon the afternoon of September 23, 1878, from a tree, about twenty-five feet, landing on the ground, but striking in his fall against the branches of the tree, and sustained the following injuries: The shaft of the humerus was separated from the head and greater and lesser tuberosities. The line of fracture closely followed the epiphyseal cartilage, although in several places the diaphysis was fractured. The shaft, slightly split, was driven through the integuments over the lower part of the deltoid muscle on its anterior aspect, tearing in its course the following parts: the insertion of the deltoid was completely stripped off with the subjacent periosteum; the coraco-brachial, teres major, and latissimus dorsi were in like manner torn off, the latter carrying with them the posterior lip of the bicipital groove. The tendon of the pectoralis major was torn off about half an inch from its insertion, and one if not both heads of the biceps was ruptured. In consequence the head and neck of the bone, deprived of periosteum, merely hung suspended by the capsular ligament and the rotator muscles. The shell of bone connected with the head and tuberosities was fissured at various portions of its circumference, as if by the impacting action of the wedge-shaped extremity of the shaft. I enlarged the wound and removed the fragments you see, namely, four and one fourth inches of the humerus, including its head. Seven weeks after the operation he could remove his coat, vest, and shirt without assistance. Ten weeks after the injury considerable reproduction of bone, even up to the margin of the glenoid cavity, was observed, with new attachments for the pectoral and latissimus dorsi muscles, as determined by Dr. C. T. Hunter. The actual shortening consequently amounted to only one and a half inches. He had perfect use of the fore-arm, could put his hand to his mouth, behind his back, and to his ear. Of course he had lost all over-hand movements.

The course of treatment pursued, and my reasons for deciding upon it, seem worthy of detail, since such injuries are but seldom seen, and, as far as I can discover, no clear rules have been laid down for their treatment. To the members of this Society who devote themselves especially to surgery, I need hardly say that no question of amputation arose in my mind;

[1] Read before the Philadelphia County Medical Society, March 20, 1884.

but to those in pure medical practice I would say that when the main vessels and nerves of a limb remain intact, the injury to the soft parts having been produced by the bone itself, not the fracturing force, almost any degree of shattering of the bones may be recovered from, in the young, without amputation. Two lines of treatment then offered for consideration, namely, the simple return of the bone, closure of the skin-wound, drainage, and trusting the case to nature; or the resection of the injured bone. Theoretically the first would have seemed the better course, promising no shortening of the limb, and the retention, in a measure, of the power of the deltoid. In reality, however, the chances of union were not one in a thousand; and if not union, then necrosis with its consequent shortening; necrosis, too, meaning months or years of inflammation and suppuration, matting the muscles together so that when recovery occurred — almost necessarily by an operation — the usefulness of the limb would be but slight. Resection, on the other hand, offered the complete removal of all injured portions of bone, and with them the most important factors of trouble after such an injury, thus permitting rapid healing, and the smallest possible amount of inflammatory adhesions between muscles, tendons, etc. If the bone had been simply returned, the risk to life would have been greater, owing to the prolonged suppuration incident upon the separation of the necrosed bone and the deep-seated abscesses so common after compound fractures. Against it was the absolute shortening of the arm, with the prospective cessation of growth due to removal of the upper humeral epiphyses.

The actual result, I think, bears me out in the course of treatment pursued, for I hardly think that in seven weeks he would have been in so good a condition, with the wound soundly healed, if I had followed what is often but falsely called the "conservative" plan of treatment. I believe that true conservatism indicated exactly what I did. The amount of shortening would not have been much less had the case been left to nature and necrosis. Had this occurred union of the severed head could not have taken place, and then the same shortening would have obtained as surely as if the epiphysis had been removed. Army experience has shown that when a portion of the upper end of the humerus is removed for injury nothing is gained by leaving the uninjured head, since it necroses.

Although not cognizant of this fact of experience at the time of operation, anatomical knowledge, general surgical principles, and experience induced me to arrive at a conclusion by *a priori* reasoning, which I have since found that extended experience had already proved.

I believe, therefore, that, theoretically and from experience, resection ought to be performed for such injuries. It is hardly necessary to say anything about the operation itself, since each case must be a rule for itself, the only point being to remove the bones with as little additional damage to the soft parts as practicable. The wound was dressed antiseptically, and when I transferred the wards to my colleague, Dr. Packard, no suppuration had occurred, and there was not the slightest inflammatory blush about the wound. He did uninterruptedly well, and the wound was soundly healed in less than seven weeks, the greater part at a much earlier date.

Sharply contrasted with this case and its results is that of the patient from whom the next specimen was removed, where the head of the humerus, luxated and partially fractured, and protruding through the skin of the axilla, was *reduced* instead of being resected. Here the tension of irritated lacerated muscles, conjoined with the necessarily imperfect drainage, kept the injured bone bathed in unhealthy pus. This with the original injury resulted in an osteomyelitis, which necessitated my amputating at the shoulder-joint. I believe had the head of the bone been removed a fairly useful limb would have been the result at the end of a few weeks' treatment, while instead, after three months of illness and risk to life, amputation was the best I could do for him.

COMPOUND LUXATION (WITH FRACTURE) OF THE SHOULDER-JOINT.

—— ——, aged thirty years, man, three months ago had his right arm caught by the belting, and drawn over a large drum in a position of extreme abduction and probably of extension. The head of the bone was luxated, the greater tuberosity torn off, and the caput humeri thrust through the axillary integuments near the anterior axillary fold. When I first saw him at the Episcopal Hospital after the accident he was very pale, with a constant discharge of pus from an opening at the site of the old wound, that is, near the anterior axillary fold, while the orifice of another deep-seated sinus was seen over the middle of the triceps, on the outer side of the arm. A probe introduced into the anterior sinus readily touched the denuded carious head of the humerus. I attempted to exsect the head of the bone, but when prepared to saw it, after its protrusion through the wound, I found such evidences of osteomyelitis as to render amputation at the shoulder-joint necessary. He did well, and recovered, but even some months later a sinus existed, doubtless the result of necrosis of some of the fragments of periosteal bone produced by that irritated structure. As before said, had the head of the injured bone been excised a useful arm would have probably resulted.

The third and last case is one where a comparatively trivial injury, owing to non-treatment at first, resulted in a condition which demanded resection of the shoulder-joint.

CHRONIC ARTHRITIS OF THE SHOULDER-JOINT: EPIPHYSEAL ABSCESS OF THE HUMERUS.

Anna M., aged seventeen years, was admitted to the female surgical ward of the Episcopal Hospital May 14, 1883. One year ago last May she fell down stairs and struck her shoulder. She was unconscious for a short time, but was soon able to walk home. The arm did not become inflamed, and seemed to the patient well. Nine months after the fall she noticed pain in the shoulder, and an elevated papule formed near the joint, which was opened at the dispensary. This relieved the pain, but left a fistulous tract discharging healthy pus. She attended the dispensary until the 14th of last May, when she was sent into the house, Dr. Seltzer, the assistant surgeon on duty, having touched dead bone with the probe. After admission she had pain from time to time, gradually increasing in intensity until shortly before operation. Other free openings for drainage were made by Drs. Simes and Kelley. The probe detected an apparent sequestrum within the humeral head. Diagnosis, epiphyseal abscess.

The operation showed complete destruction of the

joint, a carious and denuded humeral head, with an abscess about the epiphyseal site containing a sequestrum. The glenoid cavity was denuded of cartilage and roughened. The portions of head and shaft, such as you see, were removed, while all the glenoid cavity was cut away with the gouge-forceps except where the long head of the biceps was attached. Further details of the operation are unnecessary. The patient was practically well at the end of two weeks. Perfect quietude of the joint at the outset might have averted all subsequent trouble.

What was the condition here after the accident? Probably the bursæ and fibrous tissues surrounding the joint were involved, and the vascular epiphyseal cartilage was congested from the jar and injury of the fall. Congestion of all these parts, instead of being relieved by complete functional rest of the articulation, with the local application of ice, leeches, etc., as appeared indicated, was kept up by the girl following her usual occupation of housework. Although in no sense markedly strumous, yet the tendency was in that direction. As the congestion increased inflammation and suppuration were set up in the bursæ, the disease spread to the articulation, gelatinous arthritis with epiphyseal abscess supervened notwithstanding the skillful treatment of my colleagues who, *too late*, had the opportunity of treating the case.

REPORT OF A SUMMER COURSE IN OBSTETRICS.[1]

BY C. M. GREEN, M. D.

THE cases included in this report were attended during the summer of 1883 by a class of six second-year students under my supervision and instruction. The report is based on the records of the students; but their observations were in many instances verified or corrected by my own.

	Cases.	Males.	Females.	Total.

Multiparæ....	34[2]	14	21	35
Total.....	43	18	26	44

The youngest primipara was nineteen years of age, the oldest twenty-three: the youngest multipara was twenty, the oldest thirty-eight.

There were two cases of ante-partum hæmorrhage: one case occurred three weeks before delivery, without apparent cause, due presumably to a slight placental detachment by painless uterine contractions. The other case, in which the hæmorrhage was considerable, occurred between the fifth and sixth months: the woman had been in a drunken mêlée and had been kicked and beaten. She was found with a temperature of 102° F. and very restless: the fœtal movements were much exaggerated. She was kept in bed for several days, and the uterine irritability controlled with morphine, and she was delivered at full term of a living child. There was one case of sciatica in the second month, and another of obstinate neuralgia in the face, head and back which lasted throughout pregnancy and ceased only several days after the termination of the labor.

POSITION AND PRESENTATION.

O. L. A.	O. R. A.	O. L. P	O. R. P.	Foot: S. A.	Head: Position Uncertain.	Total.
29[3]	3	1	2	1	8	44

The eight cases in which the diagnosis of position was not made were not reached by the attendant until after the child was born, or until after rotation had occurred which brought the head into the conjugate diameter of the pelvic outlet.

AVERAGE DURATION OF THE STAGES OF LABOR.

	Cases.	1st Stage.	2d Stage.	3d Stage.
Primiparæ....	5	13 h. 44 m.	1 h. 23 m.	17.4 m.
Multiparæ....	27	8 h. 44 m.	45 m.	16.5 m.

In a recent work by Dieterlein of Paris on The Natural Delivery of Primiparæ, which is reviewed in the *Centralblatt für Gynäkologie*, No. 47, 1883, the average duration of first labors is placed at 15 hours: of the five cases in this report the average duration was 15 hours 24.4 minutes. The duration of the expulsive stage is placed by Dieterlein at 1 hour 15 minutes: in my five cases the average duration of this stage was 1 hour 23 minutes. Dieterlein bases his calculations upon cases below thirty years of age; for those above that age the labor is correspondingly longer, especially the second stage. My cases were between nineteen and twenty-three years old and therefore come within the limits of those on which Dieterlein based his calculations.

THE THIRD STAGE.

In all the cases but two the placenta was expelled by the uterus or expressed by the method of Credé: in two cases it was necessary to introduce the hand.

There were two cases of moderate post-partum hæmorrhage, which yielded readily to ergot, ice and compression of the uterus; and one case of severe hæmorrhage, which was finally checked with injections of iced-water and vinegar.

Of the placentæ one was very large and had several cretified nodules and plates. In one case the cord had two small diverticula about six inches from the umbilicus: in another, the cord was forty-eight inches long and was twice wound about the child's neck. In the case of twin labor the placentæ and membranes were distinct, and the fœtuses were male and female.

STATISTICS OF THE PERINÆUM.

Of the thirty-four multiparæ the perinæum was in no instance ruptured: of the nine primiparæ the perinæum escaped rupture in six cases. In one of the three cases in which rupture occurred the tear was slight and required no operation. In the second case, in which podalic version was performed, the perinæum was torn superficially for half an inch: the tear was

[1] Read before the Boston Society for Medical Improvement, April 14, 1884.

[2] Including one case of twin pregnancy.

[3] In two cases the head was extended and the brow presented.

lightly dusted with iodoform, the vagina kept clean with a one per cent. carbolic acid solution, and healing took place. In the third case, the patient being exhausted after a first stage of twenty-four hours' duration, Dr. G. P. Twitchell, in my absence, very kindly attended and delivered with forceps: the head was arrested in the superior strait, and in the extraction the perinæum was torn nearly to the sphincter: three sutures were inserted by Dr. Twitchell, the vaginal douche employed, and perfect union took place.

AVERAGE FŒTAL WEIGHT AND LENGTH.

	Cases.	Weight.	Length.
Males.....	16	8 lbs. 14.25 oz.	19.7 inches.
Females ..	24	7 lbs. 5.00 oz.	18.9 inches.

The largest boy weighed 11.25 lbs. and measured 20.0 inches.
The smallest boy weighed 6.00 lbs. and measured 18.5 inches.
The largest girl weighed 11.00 lbs. and measured 21.0 inches.
The smallest girl weighed 3.50 lbs.

THE PUERPERIUM.

There was one maternal death, that of Frau R., a Bavarian, thirty-seven years of age, who had had nine children and one abortion. When about six months advanced in this, her eleventh, pregnancy, she had double pneumonia under the care of a Boston Dispensary physician, during which sickness she said she raised much blood. Three years before she had had acute rheumatism with heart complication. I first saw her when she was about seven months pregnant and found her very weak, with extensive œdema of legs and feet, and a loud, systolic, apex murmur due to mitral insufficiency: she became deeply cyanosed on slight exertion. She was treated with digitalis and acetate of potassium, which greatly reduced the œdema and improved the respiration: she also took iron, and by the time her labor was at hand she was in a tolerably good condition: nevertheless I looked forward to her delivery with some apprehension. Her labor was tedious, lasting twenty-four hours, but was in every way normal until after the placenta was expelled, when there was moderate hæmorrhage: this was promptly controlled; but it recurred with some severity within two hours, and was again checked with pressure and ice. She did well up to the tenth day, the temperature never exceeding 99.5° F., when she took cold and suffered a return of her former symptoms: she was not seriously sick, however, until ten days later, when there was found to be dullness and bronchial respiration from the angle of the right scapula to the base of the lung, with moist and sibilant râles. She was then removed to the City Hospital, where death ensued in two days, three weeks after labor; but although occurring in the puerperal period, the fatal issue can be only indirectly, of course, ascribed to childbirth.

The other cases convalesced normally. Thirty-eight mothers suckled their infants, and three more could have done so had their infants lived. In two cases only was the mother unable to nurse.

The infantile mortality amounted to four cases: —

(1.) The fœtus weighed ten pounds and was born healthy; but the mother's milk failed in three or four days, and the child succumbed to bottle-feeding when three weeks old.

(2.) A quintipara, thirty-five years of age, suffered with palpitation, dyspnœa, cough, neuralgic pains and difficult locomotion for two weeks or more before delivery, and was wholly unable to walk in the last week. Her abdomen was greatly distended by dropsy of the amnion, and an enormous quantity of liquor amnii escaped when the membranes ruptured. A feeble, female child weighing five and one quarter pounds was born after a labor lasting seven and a half hours: respiration was established by alternate immersion in hot and cold water; but the child survived only two and a half hours. The placenta was enormous: the cord was long and wound once about the child's neck. There was moderate post-partum hæmorrhage, which was controlled with ergot and ice: the woman made a normal convalescence.

(3.) The third instance of fœtal mortality occurred in the case of a nonipara affected with moderate hydramnios. The child was much emaciated, weighed four and a half pounds, and survived only three hours. Throughout the progress of the case the woman persistently refused vaginal examination on account of her experience in her last preceding labor: on that occasion, she affirmed, her attending physician, after vaginal examination, informed her that delivery would not take place for several days; he therefore gave her a sub-cutaneous injection of something, presumably morphine, and left her. On awakening the woman found her child born, and strangled with the cord wound three times about its neck: she therefore concluded that treatment was dangerous, and that vaginal examination was of no use except, to use her own words, "to gratify a morbid desire on the part of the physician."

(4.) The fatal issue in the remaining case was due to imperforation of the anus. The head presented, O. R. P.; but it was arrested high up: forceps were therefore applied and the head brought to the pelvic floor: anterior rotation then took place and the labor terminated normally. The cord was four feet long and was twice coiled about the child's neck. The child weighed seven and a half pounds and was apparently healthy: the atresia ani was overlooked at the time and was not discovered until the next day. Another day was consumed in obtaining consent to an operation, and on the morning of the third day an attempt was very kindly made by Dr. Beach at the Massachusetts General Hospital to establish an opening with the bowel: as yet there had been no vomiting and the general condition was good. When the child was placed on the table meconium was first observed oozing from the meatus. There was a slight dimple at the proper place for the anus, and here a careful dissection was made in the hope of entering the rectum. At a depth of about one and a half inches a cavity was opened and about an ounce of meconium escaped: it was thought at the time that the opening was made into a fistulous connection between the bladder and the rectum. The child survived the operation for thirty-six hours; but during this time there was no further escape of meconium: no autopsy could be obtained.

OTHER CASES OF INTEREST.

(1.) Super-rotation: —

This phenomenon was observed in a fifth labor with a small child: the head presented, O. L. A., and the occiput normally rotated to the arch. After the birth of the head, however, instead of the usual rotation of the shoulders, a complete rotation took place, the child's face turned to the mother's left side, the left shoulder

came to the arch, and the child was born as if originally in right position.

(2.) A case of chronic Bright's disease with severe uræmic vomiting: —

This occurred in a nonipara, thirty-five years of age, in whose second pregnancy premature labor had been advised on account of severe vomiting: the advice was declined, however, and the child was born still. Her sixth, seventh and eighth children were also stillborn coincidently with uræmic vomiting. In the present instance labor set in two days after severe vomiting began and progressed normally: no medicinal treatment succeeded in checking the vomiting until, after the child was born, croton oil was given to the extent of free catharsis, with ice to epigastrium and head. The child was born alive and the woman made a good recovery, so far as the labor was concerned.

(3.) A case of suppression of urine: —

B. C., aged twenty-two, who had never menstruated since her first pregnancy, and now pregnant for the third time, was seized, when about six months advanced, with vomiting, severe headache, œdema of the legs and a gradual suppression of urine. On the day before total suppression the amount passed in twenty-four hours was only two ounces: the specific gravity was 1.018, there was a trace of albumen, a little blood and renal epithelium, and hyaline and fine granular casts. Under the use of elaterium, digitalis, and acetate of potassium the kidneys resumed their function in forty-eight hours; rectal injections of chloral hydrate and bromide of potassium were employed, but failed to relieve the headache. One month later the symptoms returned and, as the child was then viable, I urged the induction of premature labor; but the operation was declined: the patient was therefore treated with saline cathartics and diuretics, and finally gave birth at full term to a living male child weighing nine and three fourths pounds. The woman made a good recovery and her urine was free from abnormal constituents two weeks after labor.

(4.) Two cases of simple flat pelvis: —

Case I. A primipara, aged twenty-one, had been in labor thirteen hours: the os was dilated, the membranes unruptured. The fœtus was in left position, the sagittal suture was in the transverse diameter of the brim, the head was extended and the brow presented. The pelvis was slightly contracted antero-posteriorly and, in accordance with the usual mechanism in such cases, the head was seeking to enter the pelvis by its bi-temporal diameter. The head was at once flexed by pressure on the brow; but with the next pain it re-extended. The head was again flexed and forceps applied; but, as might have been expected, the first traction again extended the head. Believing that in such cases version affords a far better chance of delivering a living child than the prolonged use of long forceps, and that, if carefully performed, version is not more dangerous for the mother than the high forceps operation, I at once performed podalic version and delivered a living female child weighing ten and one quarter pounds. The perinæum was torn half an inch, but healed with the use of iodoform and the carbolized douche. The woman's temperature never exceeded 98.5° F., and she made a normal convalescence.

Case II. A sextipara, aged twenty-nine, had been in labor twelve hours: the fœtal position was left, the sagittal suture was in the right oblique diameter of the pelvis, the head had engaged by its bi-temporal diameter and the brow presented: the os was dilated and the membranes unruptured. The head was at once flexed, the membranes ruptured and forceps applied at the superior strait; but two efforts at traction resulted in again extending the head. The conjugate diameter was slightly contracted and it seemed to me clear that it would be unwise to again attempt delivery with forceps: I therefore determined to substitute the shorter, bi-mastoid diameter for the bi-temporal, and at once performed podalic version. The extraction was difficult, as the child was very large: the arms were brought down as soon as within reach; but for some moments it seemed impossible to extract the head. Aided, however, by the powerful, evenly distributed, downward pressure of the attending student I finally delivered an asphyxiated fœtus which weighed eleven and one quarter pounds. The child was resuscitated after half an hour's exertion and subsequently did well: the mother made a rapid and normal convalescence.

(5.) A case of symmetrically contracted, or æqualibiter justo-minor, pelvis, with slight scoliosis: —

The patient, twenty-four years of age, was delivered of her first child when nineteen years old: forceps were used and the child was stillborn. Her second child was born naturally one year later, but lived only fifteen minutes. She had been in labor with her third child sixteen hours when I saw her: the os was fully dilated two hours before, the membranes had ruptured and the expulsive pains were strong but ineffectual. The head had engaged in the right oblique pelvic diameter, the position was left and the head was markedly flexed: the fœtal heart was beating. I applied forceps immediately and with some difficulty delivered in twenty minutes a living female infant weighing eight pounds, the head maintaining throughout the extraction a position of extreme flexion. The child did well and the mother made a rapid and normal convalescence.

From the previous obstetric history of the patient, from inspection of the pelvis, and from the peculiar mechanism of the labor it was evident that there was pelvic deformity: subsequently therefore I made careful measurements with a view to determining the nature thereof. The woman was below medium stature and her bones were small and delicate. There was no history nor physical evidence of rickets except a slight scoliosis which resulted in tilting up the pelvis on the left side, whereby the left iliac crest was about an inch higher than the right: there was no imperfection in the gait, nor could I detect that there was any compensatory curvature of the sacrum. The external measurements of the pelvis were as follows: —

	Normal Average.	This Case.
Circumference of pelvis	90 cm.	77.0 cm.
Between iliac crests	29 cm.	25.0 cm.
Between ant. sup. iliac spines	26 cm.	23.5 cm.
External conjugate	20 cm.	17.0 cm.

It was evident from these measurements that the pelvis was contracted in all its diameters, and so far as I could detect the contraction was a symmetrical one. By computation from the external and the diagonal conjugate I estimated the conjugata vera to be from 8.0 to 8.7 c. m., that is, from 3.2 to 3.5 inches, — a contraction

of from 0.5 to 0.8 of an inch. There was of course no means of accurately measuring the transverse diameter; bat I estimated that the contraction in this diameter was about 0.5 of an inch.

The mechanism of the labor was quite characteristic of the justo-minor pelvis; that is, the head entered the pelvis in an oblique diameter and passed through the canal in a state of extreme flexion; whereas in the simple flat pelvis, or in any case where the conjugate is contracted and the transverse diameter of normal length, it is usual for the head to enter by the transverse diameter with more or less lateral obliquity of Naegele: in this latter class, too, instead of assuming a position of marked flexion, it is the rule for the head to extend and enter the pelvis, if at all, by the bi-temporal diameter, as illustrated in the two preceding cases.

From the existence of the lateral curvature of the spine, presumably of rachitic origin, and from the fact that the diminution in the distance between the iliac crests was somewhat greater than that between the spines, and again from the fact that the conjugate was perhaps a trifle more contracted than the transverse diameter, I was at first led to believe that this pelvis should be classed as of the generally, asymmetrically contracted, flat, rachitic variety. But the mechanism of the labor was not such as obtains in that class of pelvis; moreover I was unable to detect other evidences of rickets, and the pelvis seemed to me symmetrical. I therefore believe that if rickets existed in early life, it was recovered from before the pelvis was affected thereby to any appreciable extent; or rather that its influence was exerted in the disturbance of nutrition which caused a premature suspension of bone-growth rather than a bony deformity.

PERIURETHRAL PHLEGMON.[1]

BY THOMAS WATERMAN, M. D., BOSTON.

THE following cases illustrate both mild and severe attacks of periurethritis, although the *most* severe and dangerous cases complicated with urinary fistula have not been met with by me.

I have retained the somewhat antiquated term *phlegmon* because the disease was first described under that title; it should be borne in mind, however, that it is to be interpreted in this paper as meaning simply an abscess, and that it has *not* a distinctly phlegmonous character, nor is there violent inflammation or gangrene of the cellular tissue. Some of the cases may appear trivial, but they are reported on account of their *rarity*, which consists in the fact that *they occurred as a complication of simple gonorrhœa*, and have nothing to do with the every-day abscesses of the penis and scrotum resulting from the urinary infiltration of tight strictures or accidental wounds of the urethra. These four cases are all I have met with in sixteen years.

CASE I. A. B. C., a police officer, thirty-five years of age, of steady good health and temperate habits, presented himself to me in 1879, with the following history, namely: three weeks previously, after impure sexual connection, he contracted urethritis of mild type, which readily yielded to the same treatment which he had employed in a former case of the disease. Three days before I saw him he had noticed a swelling on the right side of the frenum. On examination I found a small globular tumor, somewhat less than a centimetre in diameter, slightly sensitive to the touch, and obviously containing liquid. I suggested incision, which was refused. Three days later he came again and showed me that it had opened spontaneously by a rather small orifice. He then stated that three years before he had had gonorrhœa, which was followed by a similar small abscess, and, he thought, in nearly the same situation. The discharge from the urethra had diminished and troubled him but little. He said that he could now take care of both clap and phlegmon himself, and I saw him no more.

CASE II. J. O. L., a mechanic, aged thirty. A short, slim, wiry man, but always in robust health. Never had any venereal disease before. On July 6, 1882, he had connection with a prostitute; two days later he detected a moisture at the meatus, and on that day or the next he felt a small lump on the right side of the frenum. Four days later it broke and discharged pus.

He placed himself under my care August 7th; previous to this time he had been treated by an apothecary who had medical aspirations. I found that he had a pretty free urethral discharge and an induration at the point above indicated, surmounted by an ulcer, the remains of the unhealed phlegmon. There were no indurated glands in either groin. I prescribed an injection of zinc acetate and an ointment of iodoform and cosmoline. In spite of his distinctly phlegmonous history, I thought at this time that he had a chancre. Six days later, as his sore was unchanged in appearance, I discontinued the iodoform and prescribed a lotion of chlorinated soda. The ulcer soon after healed, but the cure of the urethritis was not complete until late in September. You will ask how do I *know* that he did *not* have a chancre. Because the history was plainly that of induration, inflammation, and suppuration; because the patient was desirous of wedlock, and dreaded to such an extent the possibility of infecting his future wife that his fears amounted almost to syphilophobia. He was hypochondriacal, frequently inspected himself with the most scrupulous care to detect the earliest secondary symptoms, and came at regular intervals to me for *cross*-examination. I had him under observation for months, and failed to detect the simplest lesion of secondary syphilis.

CASE III. B. R., a lawyer, aged thirty-seven, stout, fat, and flabby. Extremely addicted to over-indulgence in sexual intercourse both at home and abroad. He had connection with two different shop-girls on February 9th and February 14th, 1880. He came to consult me February 17th, having noticed a moisture at the meatus the day previous. Two days later he had chordee. Nothing unusual occurred until March 5th, when an induration was noticed on both sides of the frenum. Fluctuation was detected five days later, and an incision was made on both sides. At the time of the incision the abscess was globular in form and bilobed by reason of the constriction exerted by the frenum. A few days later a probe could be passed through from one wound to the other beneath the frenum. At about this time I incautiously (as it proved) one day told him that the wound was now fistulous, and that it would be extremely difficult if not impossible to heal it without dividing the frenum. It seems that he had

[1] Read before the Boston Society for Medical Observation, February 4, 1884.

had a fistula in ano some years before and was not pleased at the prospect before him. Without informing me of his intention, he went immediately to the surgeon who had treated him for the anal fistula and showed him his penis. He was then rather bluntly and gruffly told that he had a chancre, and that he had secondary symptoms at that very moment. Back he came to me in terror and told me the story. I carefully examined him, and finding no indurated glands in the groins, and not a trace of secondary syphilis, I endeavored to reassure him. He had at this time a patch of ordinary herpes on the lower lip. I then went with him to Dr. F. B. Greenough, who, after hearing his story and examining the lesion, coincided with me in the diagnosis of periurethral abscess and dissenting from the "snap" diagnosis of the surgeon referred to above. A seton was suggested; it was introduced and retained for a considerable time. No benefit ensued from its use either before or after removal.

May 29th the frenum was divided, producing a large, flat, ulcerated surface, and a variety of stimulating applications succeeded each other in a vain attempt to induce it to heal. Its centre was somewhat depressed, and this was frequently probed, but neither the finest probe nor colored urethral injections ever revealed any communication with the urethra.

September 5th the patient consented to an operation. He was accordingly etherized, and a Curtis's sound introduced to distend the urethra to its fullest extent at the site of the ulcer. The granulating surface was carefully pared off as deeply as was consistent with preserving the integrity of the urethra, and the indurated margin refreshed. The edges of the wound were then brought together longitudinally and united with several fine sutures. All went well for a few days, the sutures had been removed, and silk floss moistened with collodion applied to support the wound. About five days after the operation an erection occurred and the edges of the wound were torn open. The upper and lower ends of the wound had healed, however, and the sore, diminished in size, granulated healthily and was soundly healed about a month later under the use of black wash and occasional touches of lunar caustic.

As this patient was a married man he was as anxious as Case II. to know positively whether or not he had contracted syphilis. He was, therefore, diligent in his personal examinations, and reported to me at regular intervals for a long time after the final cure. Four years have now elapsed, but no secondary lesions have ever appeared. His gonorrhœa ceased coincidently with the cure of the phlegmon.

CASE IV. E. W., a clerk, aged forty-eight, short, slim, cachectic, never possessed of robust health, contracted syphilis twelve or thirteen years ago and never entirely cured. Occasionally has plantar psoriasis. Eight years ago his first attack of gonorrhœa appeared, which was accompanied by a superficial abscess beneath the fossa navicularis at the left of the frenum. It opened spontaneously and healed readily. One year and a half later a second attack was followed by abscess on the right side of the frenum. This was incised and also quickly healed. Four or five years ago a third attack of gonorrhœa was contracted. An abscess then formed higher up the penis about half way between the glans and the peno-scrotal angle and in the median line. This was incised by an apothecary and was not completely healed for ten months or a year afterwards. An indurated lump, movable beneath the skin, always persisted at the site of the abscess.

He came to me December 11, 1880, with this history, and stated that he had again caught the "clap," and that ten days after the discharge showed itself the lump before mentioned began to enlarge. On examination I saw a large, shiny, tender, purplish tumor surrounded by boggy œdema, and not distinctly fluctuating. Seven days later it was as large as a walnut and evidently full of pus. There was little or no constitutional disturbance and no dysuria, although the pressure of the tumor upon the urethra had diminished the force and size of the stream of urine somewhat. The abscess was freely incised parallel with the length of the penis, and poulticed. About a week after the incision a sinus four centimetres in length was discovered extending upwards towards the bulb. The patient declined another incision at this time, and efforts were made to cause the sinus to heal by means of carbolized injections and packing with medicated lint. These methods were fruitless, and one month after the first incision the sinus was freely laid open with scissors, no opening into the urethra was found, and the resulting wound was induced to granulate from the bottom. Three weeks later the cure was complete, the discharge from the urethra having ceased previously. An examination some months later revealed no induration at the site of the cicatrix.

Periurethritis, periurethral phlegmon or abscess is rare, half a dozen cases probably being a large number for even a specialist to see in thrice as many years. It is said that folliculitis or follicular abscess of the penis is still more uncommon. The seat of attack is similar in the two affections, but they are anatomically distinct. The former is an inflammation of the cellular tissue which connects the skin of the penis with the corpus spongiosum, and always terminates in suppuration. The latter is an inflammation of the follicles of Morgagni, which open into the urethra and is cystic in character. Owing to the rarity of periurethral phlegmon its literature is meagre. C. Hardy, Ricord, Fournier, Bumstead, Otis, Van Buren, and Keyes all devote some space to it, the French writers more particularly.

Periurethral phlegmon is periurethritis ending in abscess. Chordee is a periurethritis, but it has no tendency to suppurate. It will be noticed that only one of the cases had chordee, and it was but slight. Suppurative periurethritis is probably never idiopathic, always resulting from acute urethral inflammation, leaving out of consideration those more common cases caused by infiltration in connection with stricture.

It appears from Cases I. and IV. that having once happened a recurrence is to be expected at each attack of gonorrhœa. Cases II. and III. had never suffered from venereal disease previously, and may be heard from again in the future. The phlegmon may be situated at any point of the urethral side of the penis from the glans to the bulb, but it is said that the points of election are the neighborhood of the frenum and the peno-scrotal angle. Those near the frenum may be limited to one side, as Cases I. and II., or both sides may be involved as in Case III. They are globular, not large, and superficial. The abscesses higher up on the penis, as Case IV., are larger, deeper-seated, occasionally retard the flow of urine, and sometimes cause constitutional disturbance. The abscess usually opens externally, and this is the most favorable termination. It may, however, break into the urethra,

and subject the patient to the grave dangers of urinary infiltration and sloughing of the cellular tissue of the penis and, perhaps, of the scrotum also. In some cases the abscess breaks both internally and externally.

In regard to treatment it is self-evident that the phlegmon should be incised freely as early as possible after suppuration is definitely established. If possible any sinuses, which may exist, should be detected at the same time, and laid open to their extreme limit. The resulting wound should then be packed with lint, and allowed to granulate from the bottom. The cure in Case III. would doubtless have been less chronic if the bilobed abscess had been opened transversely, and the frenum divided in the first instance. Much troublesome induration, which prevented cicatrization, would thereby have been avoided. The sinus in Case IV. should have been laid open when the abscess was incised, and would have been if the patient had been etherized. If the abscess breaks into the urethra a counter-opening may be made externally at once, which is probably the most prudent course, or we may wait for the possible occurrence of infiltration, which Fournier says does not commonly happen. A urinary fistula may be the termination of a phlegmon, and is more liable to result near the bulb than towards the glans. Hardy says that "at the latter place it gives rise to an accidental hypospadias which is difficult to cure."

Perhaps the most interesting practical point connected with this complication of gonorrhœa is its liability to be confounded with a primary syphilitic lesion, as illustrated by Cases II. and III. When it is a typical phlegmon, already containing pus, the diagnosis is easy. In the initial stage of induration, however, on one side of the frenum, before suppuration is established, the physician may well be pardoned for postponing a positive opinion until more light is thrown on the case by subsequent developments. Again, as in Case II., where a patient does not present himself until the phlegmon has opened, and it is seen for the first time in the condition of a small granulating ulcer with indurated base, expectant treatment should be practiced, and a long period of incubation allowed to occur before a final opinion concerning the nature of the lesion is given.

REPORT ON ORTHOPEDIC SURGERY.

BY E. H. BRADFORD, M. D.

LENGTH OF LIMBS AFTER DISEASE OF THE JOINTS.

THAT limbs, after resection of the joints and after disease, sometimes cease to grow or grow less rapidly than the healthy limb is a well-known fact, and has been explained as an effect of the disuse of the limb, or as a result of the disturbance of the nutrition of the bone through injury of the line of the epiphysis. Wolff,[1] after a number of measurements, has come to the conclusion that neither of these is sufficient to account satisfactorily for the result. A shortening takes place not only of the bones which were affected by the disease or the operation, but also those which apparently have been healthy. For example, ten or twelve years after disease or resection of the hip a shortening of the femur will be noticed, and a shortening of the tibia and fibula to a slight extent, while a much more marked arrest in the size of the foot and in that of the patella is almost constantly observed. And after affections of the knee and shoulder a lengthening of the humerus and femur is sometimes noticed. Diminution in the size of the patella is not observed in affections of the knee out of proportion to that of the limb, while a shortening of the foot is noticed.

The explanation of these facts offered by Wolff is that a primary joint affection is followed by a secondary affection of the nervous system of the limb, which gives rise to an arrest of development of the bones of the limb. Analogous to this is what is seen in infantile paralysis and progressive muscular atrophy, and in the nervous muscular atrophy described by Valtat in inflammations of the joints.

[1] Vide Berl. klin. Wochenschr., 1883, Nos. 28–30.

TUBERCLE BACILLI IN JOINT AFFECTIONS.

Koch, Marchaud, Schuchardt, and Krause have all come to the conclusion that the bacillus plays an important part in the ætiology of fungous osteitis and arthritis, but they agree as to the great difficulty in demonstrating the presence of these organisms as the number present is relatively small. Müller has, at the Göttingen Clinic, been able to examine for the presence of bacilli the bones from thirty cases removed by resection. In the majority of cases a few bacilli were to be found after examining a number of sections, but in a number of specimens of undoubted tuberculous ostitis the result was entirely negative. In one case, however, of coxitis, in the very earliest stages, appearing a short time before death from phthisis, and manifesting the symptoms of pain and contraction of the limb, and at autopsy a focus of tubercular granulations at the head of the femur, near the insertion of the ligamentum teres, perforation of the cartilage, pannus of the cartilage around the spot of cartilaginous perforation, and congestion of the synovial membrane, the tubercles in the granulations were numerous, but not caseous, but on examination a very large number of tubercle bacilli were found, and the writer suggests that, possibly, the bacilli may, in the earlier stages, be present in larger numbers than after the ostitis is more destructive, though the matter is one which will need further investigation. It would appear, however, that unlike those in tuberculosis of the lung the bacilli of chronic disease of the joints promise but little for diagnosis or prognosis.

TREATMENT OF TUMOR ALBUS BY ARSENIC.

Landerer[2] reports several cases where marked improvement followed the administration of arsenic internally (0.004, 0.008, and 0.012 in pills daily for several weeks), and in one case the subcutaneous injection of an aqueous solution of acidi arsenicosi, 1 to 1000.

The writer does not regard arsenic a specific against tuberculosis, but, relying on experiments on guinea-pigs, he concludes that it increases the resisting power against tuberculous infection.

STATISTICS OF RESECTION OF THE KNEE.

Mensing[3] has collected eighty cases of total and three of partial resection of the knee, operated upon at Kiel, and nine operations of removal of a wedge-shaped piece of bone for rectangular anchylosis. Forty-eight of these (52.01 per cent.) were discharged well. The average shortening was two and one half centimetres,

[2] Centralblatt f. Chirurgie, November 24, 1883.
[3] Centralblatt f. Chirurgie, No. 49, December 8, 1883.

and flexion only occurred in two cases; two had good motion; one only slight motion. From thirty-two of these later information as to their condition was obtained, and in three cases a moderate flexion had taken place; in two a relapse had occurred, followed in one case by a second resection, and in another by amputation.

In thirty-four patients the excision was not perfectly successful (that is, thirty-seven per cent.), fourteen undergoing a subsequent amputation, and twenty having an unhealed sinus at the time the patients left the hospital. Of these twenty the ultimate results of thirteen were obtained: in ten cicatrization took place; three died. Of the fourteen secondary amputations ten recovered, and two died.

Ten patients who underwent excision at the clinic died directly from the operation, five of pyæmia, one of Bright's disease, one of general tuberculosis, two of exhaustion, one of hæmophilia.

These operations were performed in the years from 1857 to 1883, and the time is divided by the writer into three epochs: First, before the introduction of Listerism and Esmarch's bloodless method; Second, after these were introduced; Third, after the introduction of Neuber's permanent dressing. The mortality in the first period in twenty-one cases was 33.03 per cent.; in the second period, twenty-three cases, was 8.7 per cent.; and in the third period, forty-eight cases, two per cent. The length of time required for healing in the first two periods averaged 129 days; in the third period eighty-nine days.

RESECTION OF THE KNEE.

Ollier[1] reports that before the introduction of antiseptic surgery his mortality in resection of the knee was eighty per cent.; since then his mortality has fallen to fourteen per cent.[2] Formerly he used excision simply as a life-saving measure, but at present he feels justified in recommending it as a means of shortening the course of the disease. In children, however, he is disinclined to perform resection for fear of limiting growth. In operating Ollier is careful to spare as far as possible the periosteum and ligaments, though the capsule or ligaments should not be spared if diseased. A straight incision is only used for traumatic cases. In fungous disease an H-incision is to be used. The two lateral incisions should be as far forward as possible in order to spare the lateral ligaments. If the patella is affected it should be removed. The bones are wired together as well as the ends of the cut ligaments, and drainage tubes are to be inserted above and below if the posterior part of the capsule is diseased. In traumatic cases a single straight incision is advised dividing the patella. This method he has only tried on the cadaver, but is recommended because the ligaments are best spared in this way. Resection is to be performed in deformity at the knee if ostitis is present. If, however, perfect cicatrization has taken place with a rectangular position of the limb an osteoclast is to be used, but one devised that the rupture should take place directly at the desired point; but in some cases osteoclasis cannot be used on account of cicatricial contraction at the back of the knee. A wedge-shaped piece of bone is to be removed in these cases, and this is best done at the point of the obliterated joint.

THE ACTUAL CAUTERY IN CHRONIC JOINT AFFECTIONS.

The routine French treatment for tumor albus is "boutons de feu" (that is, touching with the galvanocautery), immobilization, repeated blisters, tincture of iodine. The want of effect produced by ignipuncture has suggested more thorough treatment, namely, the pushing of the cautery directly into the bone and exciting a cicatrizing sclerosis. It is said that simple ignipuncture succeeds where it is not indicated, and fails where it is.

Curetting is a favorite method of Volkmann, Schede, Boeckel. It is a method, according to M. Vincent, either insufficient or excessive, excessive in simple granular fungous synovitis, and insufficient where excision is demanded, it being impossible to completely remove by a curette all the foci of disease. Ollier's method is described as follows:[3] Before the operation the patient is to be thoroughly washed, the site of incision being scrubbed with soap and brush, and any hair that may be present shaved. The operation consists of arthrotomy, the line of incision being parallel to the axis of the limb, either a knife being used cleansed by heat or a point of the Paquelin thermo-cautery. The incision should divide the skin and all lardaceous tissues, and if necessary the joint should be completely exposed by a cross incision. If the fungosities are tolerably superficial, the Paquelin cautery will be sufficient, but in extensive cases the old-fashioned "cautery irons" will be needed to riddle the diseased bone.

In young subjects the cauterization should be pushed quite far, and is followed by excellent results. Irrigation by an antiseptic completes the operation. Iodoform is then dusted on the wound, and the limb wrapped in boracic acid compresses wet in carbolic, carbolic gauze and salicylicized cotton, mackintosh, and bandages. This dressing should reach up to the middle of the thigh in cases of affections of the knee, and the whole should be wrapped in a silicate bandage, strengthened by card-board or light wood. A second dressing is not applied for three weeks or a month.

DISEASE OF THE BONES OF THE PELVIS.

The initial site of the chronic disease of the joints is placed by the best authorities at the line of junction of the epiphysis with the diaphysis. "The point of election," to quote the words of Ollier, "is not the epiphysis but the 'region juxta' epiphysaire." Gouillaud and Ollier have pointed out that this is also the case in pelvic osteitis. Pelvic caries may be either intra-cotyloid, not distinguishable from hip disease, or pericotyloid, with difficulty separated from hip disease, or marginal, the site being partly dependent upon the age at which the inflammatory process is awakened, as before puberty the most active growth is at the junction of the three pieces of bone which form the ilium; after puberty the most active cellular process is on the margin at the epiphysis there. Acetabular hip disease is much more common than is supposed; it is regarded by the writers as at least as frequent as the femoral variety.

The most common age for marginal pelvic disease is twenty-three years, and the places most frequently attacked are the crests of the ilium, the posterior iliac spines, and the apophyses of the sacrum, anatomi-

[3] Vincent, Arthrotomie Ignée, Revue de Chirurgie, January 10, 1884.

cal points where the epiphyses are developed even in early adult life.

The early symptoms of this marginal pelvic caries are chiefly indications of visceral affections, that is, the intestine and bladder, and the appearance of abscesses either in the bladder or intestine.

In childhood frequent aspiration of abscesses and expectation are indicated, unless the hip is threatened. In case of pelvic hip disease excision naturally gives the best drainage, and perforation of the acetabulum so far from being a contra-indication to that operation imperatively demands it.

In the adult opening of the abscess is indicated, whatever its seat. If intra-pelvic, the pelvis can be trephined, an operation first done in 1778 by Boucher, and repeated with success by Verneuil.

SACRO-ILIAC DISEASE.

This affection is so rarely observed that the records of four cases are of value.[1]

One patient was a child six years of age, who recovered. A second was observed in a woman, who recovered after long suppuration. In the third case death took place after long suppuration, and an autopsy revealed extensive ostitis. The fourth patient died of phthisis, but underwent an operation of removal of carious bone by chiseling through the ilium. Riedel mentions having seen three cases, two in children of five and fourteen, one in a woman of thirty. The first was operated on by extraction of the sequestrum through an incision dividing the gluteus maximus, and in the second and third cases the iliac bones were trephined. Recovery took place in the first and third patients, the second dying of extensive caries.

REPRODUCTION OF BONE AFTER RESECTION.[2]

Experiments have been made on young dogs to determine this matter. The lower end of the femur, the patella, and the semilunar cartilages were removed subperiosteally, the saw being always applied in the line between the epiphysis and diaphysis. A complete regeneration took place, the bone consisting of the ordinary spongy bone tissue, and covered to a greater or less extent at the end with cartilage. The bone began to be developed partly from the periosteum of the diaphysis, partly from the marrow, and partly, but to a less degree, from subperiosteal tissue which had surrounded the excised portion, the formative activity of the periosteum being greater at a later stage. The surface of the tibia suffered little alteration except where the differences in pressure or mobility affected the growth of the bone.

THE FEVER OF GROWTH.[3]

Bouilly has described and named "la fièvre de croissance," the symptoms sometimes seen in growing children, which are probably analogous to those grouped in popular language under the head of "growing pains." Bouilly is inclined to classify it as a light form of osteo-myelitis which runs its course without suppuration, and is most prevalent at the time of the most rapid growth. A comparison may also be suggested with the view of the nature of rickets which has been advanced, that the disease is characterized by a faulty circulation of the bones caused by imperfect development. Bouilly's "fièvre de la croissance" appears in three forms: (1) acute, which is the lightest and most frequent; (2) an acute form with severer symptoms; (3) a chronic incipient form. All these varieties have fever and pain in the bones, chiefly in the juxta-epiphyseal zone, most frequently near the lower epiphysis of the femur. The short and flat bones are seldom affected. The joints are almost never affected, but exceptionally effusions into the joint are seen. In the lightest form the symptoms pass in thirty-six hours, in severer cases the fever may last several days and even be attended by some typhoidal symptoms, followed by a sudden fall of the fever and recovery. The chronic subacute form may last for months, and relapses may occur; the prognosis is, however, favorable. Quinine and tonics are recommended. The disease may appear from the fifth to the twenty-first year, and the symptoms may be brought on by long walks, strains, or fatigue.

ÆTIOLOGY OF LATERAL CURVATURE.[5]

Sklifosowski[4] found, on examining twenty-one cases of scoliosis, in seventeen shortening of one limb, in four the shortening was so slight as to escape observation. In eleven the right thigh was longer than the left; and in twelve the right leg was lengthened. In nineteen young persons not suffering from lateral curvature, in five a difference in length of the lower extremities was observed, and the writer concludes that a difference in the length of the lower extremities alone could not account for the existence of lateral curvature, and in all probability some disturbance in the development and growth of the bones of the spine is influential in bringing about the distortion. Confirmatory of this he found other abnormalities in the development of the skeleton (genu valgum, pes planus, valgo planus) in two thirds of the cases suffering from lateral curvature.

THE NATURE AND TREATMENT OF RICKETS.[5]

Kassowitz is of the opinion that rachitis results from an abnormally increased vascularization of the bone-making tissues. Wegner reports as a result of a series of experiments upon animals the opinion that phosphorus given in small doses for a length of time gives rise to a diminution in the amount of the medullary tissue and arrests the normal transformation of osseous tissue into medullary cells, while large doses cause the reverse condition, namely, an increase in the medullary transformation, that is, an artificial osteo-malacia. Kassowitz, therefore, has in a number of five hundred and sixty patients administered phosphorus with beneficial results, namely, a diminution of the nervous symptoms, spasm of the glottis, restlessness, sleeplessness, and an improvement in the ability to walk, an improvement in the general condition of the patient, as manifested by an increase in weight and appetite. The phosphorus is administered with cod-liver oil in from half a teaspoonful to two teaspoonful doses daily, of a mixture of 0.01 of phosphorus to 100.0 of cod-liver oil, or in older children the medicine can be given in pills commencing with a dose of half a milligramme.

OSTEOTOMY IN OBSTINATE CLUB-FOOT.

A discussion on this subject took place in the Societé de Chirurgie[6] in Paris, occasioned by a paper by

[1] Vide Tilling, St. Petersburg Med. Woch., 1883, No. 29. Centralblatt f. Chir., 1884, No. 3.
[2] Vide Bajardi, Centralbl. f. Chirurgie, No. 42, October 20, 1884.

Dr. Beauregard reporting successful cases. The majority of the French surgeons were strongly opposed to this method of treatment, Guerin, Anger, and Verneuil being especially so, the former claiming that except in the club-feet of adults no deformity of this sort existed which could not be corrected by tenotomy and apparatus. Polaillon and Chauvel and some others thought the operation might be of advantage in talipes equino-varus of adults.

E. Boeckel [1] makes a distinction between osseous and tendinous club-foot; the first of these can be cured by tenotomy and apparatus; in the second class tenotomy is of no use, and though improvement follows a long-continued course of treatment by massage and apparatus, yet in his experience relapses easily follow when apparatus are discontinued, the cause of this being the curling inward of the hindmost foot at the end of the step, caused by the instinctive turning of the foot inward, to aid the gait when the dorsal flexion is only possible to a right angle. Boeckel thinks that the chief hindrance to correction of the foot is in the deformity of the tarsus, which is radically relieved by extirpation of the astragalus, which he has performed four times with perfect success.

TREATMENT OF SPINAL ABSCESS.

Lacharriere [2] has collected twenty-eight cases treated by antiseptic incision dressed with strict antiseptic precautions. Of these five died, fourteen were healed without sinuses, and in nine the result was uncertain. Twenty-one cases were treated by curetting the abscess walls, and of these two died, fourteen were healed, and in five sinuses were left. This latter procedure is not possible except in abscesses of the lumbar region and of the back. In psoas or iliac abscess such a treatment is not only not always possible but in certain cases dangerous.

Reports of Societies.

PROCEEDINGS OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M. D., SECRETARY.

April 14, 1884. The President, Dr. Charles D. Homans, in the chair.

SPONTANEOUS PHLEBITIS.

Dr. W. C. B. Fifield reported the case, which is unique in his experience. The patient, an anæmic young lady who had been occasionally treated for neuralgia during many years, had a temperature of 104–105° F., with a rapid pulse. She was dizzy, and complained of pain indefinitely situated near the great sciatic notch, and of heaviness of the left lower extremity. Being uncertain as to diagnosis, the speaker had called a competent consultant, who, while also unable to form a positive opinion, believed the trouble to be mainly hysterical, and cited an asylum case in support of this belief. The treatment agreed upon was unsatisfactory in its result, and the following evening Dr. C. E. Stedman was called in consultation.

By this time a new symptom had developed, a swelling of the leg, which was, however, still so slight as to be detected only by measurement. Pain, with high temperature and rapid pulse, continued. It was agreed to alter the last night's prescription of bromide of sodium with hyoscyamus to the bromide with chloral, and with this the patient got some rest. The case, however, went on, the calf swelling enormously and the thigh to twice its size, both pitting and assuming a white marble look, the pulse becoming 130. The treatment consisted in brandy and opium until the pain was over, and then brandy and quinine. As two grains of quinine every four hours caused cinchonism, it was omitted, thirty drops of tincture of chloride of iron being substituted. This drug caused the patient to vomit, as it often does her as well as some others, and it was in turn omitted. Dr. Fifield can find no accounts of spontaneous phlebitis. Trousseau reported it as an accompaniment of rheumatism and claimed that the cases got well with quinine and stimulants. He did not state the condition of pulse and temperature. Simpson and others have reported it as a puerperal complication, and supposed it to be of septic origin. We know that varicose veins get inflamed with formation of blood clots. The speaker had seen phlebitis as a complication of dysentery.

DR. JAMES AYER mentioned its following typhoid.

DR. C. E. STEDMAN said that a year seldom passed at the City Hospital when there were not one or more examples of phlebitis in patients, mostly men, in the third and fourth weeks of typhoid fever.

DR. C. D. HOMANS said that the nearest approach to spontaneous phlebitis that he had seen had been with a fractured thigh in which good union had occurred. He had seen it after amputation for accident in a patient over sixty. It is not very uncommon after typhoid, and in his cases has got well after a time.

DR. FIFIELD replied that he had seen phlebitis after dysentery, but never after typhoid. Arteritis occurs as a sequel of typhoid, and he mentioned a case at La Charité in Paris amputated by M. Gosselin in 1875 for gangrene, and dying from gangrene of the other leg. Both femoral arteries were found to be plugged.

EXTERNAL URETHROTOMY, WHEELHOUSE'S OPERATION.

DR. FIFIELD thought that this operation, comparatively little known here though well known abroad, was sure to grow in favor. He has done it once, so far as he knows being the first surgeon in the United States to do the operation, and has seen it done once. In the common way it is not always easy to find the urethra. In cases of extravasation of urine Bryant prefers to pass a catheter, or to open the urethra. This is more easily said than done. The speaker never leaves a catheter in, but makes incisions and tries to introduce it three or four days later. Since his own operation he has seen it very well done by Dr. H. L. Burrell.

DR. C. M. GREEN read a paper on

A SUMMER COURSE IN OBSTETRICS.[1]

DR. O. W. DOE said that he had had two recent cases in which not so much as a drachm of milk could be got at any time.

DR. GREEN said in reply to a question by Dr. Fifield as to how he successfully performed version and extraction of such large children, that the version was done in the usual way, but that great care was taken not to extend the arms and head. In the first case traction was made only during the pains: in the second case, owing to the absence of pains, the uterus was followed down with the hands of the assistant. As soon as the arms could be reached they were brought down. In the second case the extraction of the head at first seemed impossible: forceps were tried without success; and finally extraction was accomplished with the aid of powerful pressure on the uterus from above.

DR. A. T. CABOT read a paper on a case of

MULTIPLE CALCULI IN THE BLADDER,

and showed the specimens. The paper will be published in a succeeding number of the JOURNAL.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

CHARLES H. WILLIAMS, M. D., SECRETARY.

FEBRUARY 4, 1884. DR. THOMAS WATERMAN read a paper on

PERIURETHRAL PHLEGMON.[2]

DR. FITZ said that the name of periurethral phlegmon should be confined to those cases in which there was a diffuse inflammation of the tissue. These cases were rather periurethral abscess, and this difference in nomenclature may have accounted for the small number of reported cases mentioned by the reader.

DR. J. W. ELLIOT then read a paper on

THE TREATMENT OF RETROVERSION OF THE UTERUS WITH ADHESIONS.[3]

DR. C. M. GREEN said that packing will often give good results even when there is subacute peritonitis or cellulitis present. He also mentioned the following case in which packing had been used: —

The patient had her last child fifteen years ago. Since then much pain, constantly recurring attacks of peritonitis, and no ability to work. Examination shows cervix torn, uterus prolapsed, external os just within the opening of the vagina. The examination gave much pain, but nevertheless a light tampon of cotton, soaked in glycerine with ten per cent. of iodoform, was inserted. The iodoform was used because it seems to relieve the local pain. Relief soon followed. She has been under treatment two months, and is now free from pain. The uterus is higher, and more in place; the adhesions are absorbing.

In a second case there were no local symptoms, and very little dysmenorrhœa; there was some headache and a general confused feeling, but the symptoms were so slight that the patient thought an examination was unnecessary; however, when this was made retroversion and adhesions were found, and treatment with a tampon was begun. In two months the uterus was brought forward into good position by replacing the tampon twice a week. Some medication was resorted to for the headaches, but without success; when, however, the uterus had been replaced these disappeared. The after-treatment was by a pessary. This was once removed for a week, but a slight retroversion returned, which was again cured by the continued use of the pessary. He thought the treatment by tampons often proved quickly successful, and that the nervous symptoms which accompany the retroversion were often the most difficult to treat.

DR. LOMBARD mentioned the treatment by manipulation repeated every two to four days for five to ten minutes. He had seen very good results from this method even when it caused considerable pain to the patient, but he thought the reader's method better, as it gave a constant and equable pressure instead of the interrupted manipulations.

In answer to DR. SABINE as to what class of cases it was not best to undertake this treatment, the reader said that in old women, long past the climacteric, where there was retroversion without any peritonitis, and, again, in all cases where there was a local acute peritonitis.

DR. C. B. PORTER then reported

A CASE OF PILO-NIDAL SINUS.

N. L., forty-two years, jeweler, entered the hospital January 11th for a fistula in ano, which had given him trouble for about two months. The patient had a large amount of hair on the chest and other parts, and on the left buttock, in addition to an ulcerated point about two inches from the anus, which had been discharging about two months, there was a pilo-nidal sinus from which a tuft of hair projected. This was laid open by a cut some three inches in length, and a large

[1] See page 389 of this number of the JOURNAL.

[2] See page 392 of this number of the JOURNAL.

[3] Boston Medical and Surgical Journal, vol. cx., p. 193.

mass of hair removed. The wound was then dressed with iodoform and charpie and myrrh, and healed readily.

Dr. Porter then reported the following case: —

DIPHTHERITIC PERINEAL WOUND; CHRONIC CYSTITIS; BILATERAL INCISION OF PROSTATE FOR REMOVAL OF STONE; ACUTE SUPPURATIVE PERITONITIS. AUTOPSY.

January 21st. L. D. V., aged thirty eight, farmer, about seven years ago first had pain on passing water. Had at that time a stricture which he claims was not of venereal origin. About a year later he underwent the operation of perineal section. Judging from the scar the incision was made through the scrotum down to the anus. There is now only a line of cicatrix. About three years ago noticed a desire to pass water very frequently; also noticed some pain both before and after passing urine. Passed small particles about the size of rice, which were hard; also passed blood at intervals. Since then his condition has been steadily growing worse. He now can retain his urine at best only ten or fifteen minutes. Has great pain at times, which he locates both in the back passage and in penis.

January 23d. Examination by Dr. Wood. Color smoky; specific gravity 1008; sediment, much; reaction alkaline; albumen, large trace. Sediment: much pus; considerable blood; little triple phosphate; one epithelial cast seen; no large excess of bladder epithelium.

January 24th. Dr. Porter passed No. 23 sound, and in the prostate the sound struck on a solid substance which gave the feeling of stone. Examination by rectum shows a dense, hard mass situated in the prostate. Seems to be immovable, and causes pain when pressed upon. The mass appears to be about as long as the finger.

January 26th. Etherized. Dr. Porter tried to introduce a lithotrite with intention of crushing stone, but was unable to get into bladder. Patient then brought down into position for perineal section. A staff was introduced into urethra. A cut was then made into perinæum about four inches long downwards and outwards. Staff was exposed, and left lateral incision made through prostate. Attempts were made to seize the stone with forceps, but without success. The prostatic incision was enlarged, and another made on the right side in a corresponding manner, in other words, bilateral incision of the prostate. After several attempts the stone was firmly clasped by the forceps, and withdrawn. A canula was then inserted, and wound packed with sponges. This afternoon canula withdrawn, and bladder washed out thoroughly with hot phenyle. Weight of stone 1320 grains.

January 27th. Patient very comfortable. Bladder washed out with hot phenyle.

January 28th. Wound doing well.

January 29th. Patient has almost no appetite. Whiskey ℥ss. every four hours. Pulse rather weak and 120. Complains of considerable pain over abdomen.

January 30th. Complains of severe pain over abdomen, and especially over right side, extending up into chest. Has a sighing respiration, which at times is a moan. Amount of urine cannot be accurately estimated, but judging from the staining of sheets it would seem to be much diminished in last two days. Patient had poultices to side and over abdomen. Subcutaneous injections of morphia, grain one sixth, this morning, which gave some relief.

At eleven A. M. had an ounce of brandy, and a half ounce repeated every half hour after twelve.

About two P. M. was transferred to Ward D. Hot poultices and hot fomentations to side and over abdomen. At five brandy increased to ℥vi. every hour. Throat dry and parched. Talks with difficulty. Lies in a sort of stupor. Moans, and can be aroused only with some difficulty. About nine P. M. had much trouble in taking stimulants. Brandy ℥vi. Beef tea ℥iii. given hourly by enema.

The rest of the night grew weaker, and died Thursday morning at five A. M., five days after operation.

The autopsy was made thirty-four hours after death by Dr. Fitz, who showed the urinary organs in continuity. He stated that the peritoneal cavity held several ounces of thick creamy pus. The peritonæum presented a moderate vascular injection, and the intestines held but little gas. The lumbar lymphatic glands were enlarged to the size of almonds, soft, gray, and injected; the afferent pelvic lymphatics contained an opaque yellow lymph.

The bladder was firmly contracted, forming a dense, unyielding mass as large as the fist, in close apposition to the anterior wall of the pelvis, and nearly filling its cavity. The subperitoneal tissue over the fundus was abundantly fatty. On opening the bladder its cavity was found to be of the volume of a small peach. The walls varied in thickness from a half inch to more than an inch, and were incapable of distention, being largely composed of a dense fibrous tissue in which opaque yellow streaks were seen, suggestive of a fatty degenerated muscular wall. The mucous membrane was thickened and of a bluish slate color, with occasional small, shallow diverticula. A bilateral wound through the cervical portion of the bladder was continued into a perineo-urethral incision. The cut through the urinary tract was over two inches in length. The lips of the perineal opening were glued together, and the general surface of the wound was coated with opaque yellow patches, firmly adherent, and representing a superficial necrosis of its tissues.

Both ureters, especially the left, were dilated, thickened, elongated, and tortuous. Each contained a considerable quantity of muco-purulent fluid. The right ureter was large as the fore-finger, the left of the size of the thumb. The renal pelves were moderately dilated, and were connected with sacculi the size of the finger tip. The mucous membrane of the pelves and ureters was thickened, rough, gray, somewhat translucent, and showed numerous varicose, injected blood-vessels.

The kidneys were diminished at least one third in size. The capsules adherent, portions of the surface of the kidney being torn away with the former. The surface was irregularly lobulated, with gray, filmy patches. On section the cortex was atrophied, the tubular regions and Malpighian bodies indistinct. The alterations described were summarized as indicative of a diphtheritic perineal wound, lumbar lymphadenitis, and acute suppurative peritonitis, chronic cystitis and paracystitis, chronic pyelonephritis, with dilatation and hypertrophy of the ureters.

Dr. Porter also reported a case of

REMOVAL OF A FRAGMENT OF CATHETER FROM THE BLADDER.

January 15th. William L. N., farmer, aged sixty-four. Patient has an enlarged prostate, in consequence

of which he has been obliged to catheterize himself for the past six years, using for the purpose a soft rubber catheter. Sixteen hours ago, while inserting the instrument, it broke in the middle of the urethra, leaving inside a piece five inches long. He immediately put his finger on the under side of the penis and felt the piece there, but on removing the finger it slipped into the bladder.

He has no pain, but says that since the accident his urine has dribbled away constantly.

Patient was etherized, and the bladder explored with a small lithotrite, but nothing was caught. A medium-sized lithotrite, with closely-fitting, finely-serrated blades, was then introduced, and after several attempts the instrument caught a small object that proved to be, when withdrawn, a little calculus the size of a pea. After a few more attempts the lithotrite seized the catheter. The blades were then locked, and an attempt was made to withdraw the instrument, after first moving it about to make sure that the wall of the bladder was not nipped. When the blades of the lithotrite reached the middle of the urethra they were held so firmly that it was almost impossible to move them. Externally there could be felt, just at the knee of the lithotrite, a large, irregular lump. In order to explore this and make sure that the wall of the urethra was not being pulled along in front of the catheter, the urethra was slit up on its under side for a distance of one inch. A director, being then introduced, felt, by the side of the lithotrite, the end of the broken catheter. Strong traction then brought out the lithotrite with the fragment of catheter caught, an inch and a quarter from its rounded end, in the bend of the instrument. The piece of catheter lay along the shank of the lithotrite, and just at its middle was a double fold which had been made by the hitching of the end of the catheter while passing through the prostatic part of the urethra; this was the explanation of the difficulty in withdrawing the instrument, and the large, irregular lump felt in the urethra. At the moment of withdrawing the catheter it broke at the point where it was grasped by the lithotrite. It proved to be a dry and brittle piece of No. 16 French (9 E.) catheter.

A No. 12 English gum elastic catheter was then fastened in the bladder, and the patient put to bed, with a bottle and tube arranged to catch the urine. One stitch was taken in the cut on the under side of the penis, and a little iodoform applied. Patient slept comfortably all night, and had no further discomfort. The catheter was removed after forty-eight hours, and the patient discharged on the third day. His temperature rose to 100° F. on the morning of the second day and the evening of the third day, being 99° F. in the mean time. It was normal at the time of discharge.

Recent Literature.

A Manual of Practical Hygiene. By E. A. PARKES, M. D., F. R. S. Sixth Edition. With an Appendix. Volume I. Wm. Wood & Co. 1883.

The publishers of the Library of Standard Medical Authors have done a good service in issuing this excellent manual in its present shape, thus popularizing a valuable work, and awakening a deeper interest in a branch of medicine too much neglected by the general practitioner.

Chapter I. treats of Water; the quantities necessary for its use by man; modes of collection, storage, and distribution; its quality and impurities; modes of purification; effects of insufficient and impure supply; its examination for hygienic purposes. II. Air; its impurities and the diseases produced by them. III. Ventilation. IV. The Examination of Air. V. Food. VI. Its Quality, Choice, and Cooking. VII. Beverages and Condiments. VIII. Soils; their conditions, constitutions, and modes of examination.

Volume II. contains a continuation of Book I. which treats of the following topics: Habitations; The Removal of Excreta; Warming of Houses; Exercise; Clothing; Climate; Meteorology; Individual Hygiene; Disposal of the Dead; The Prevention of Disease both Specific and Non-specific; Disinfection and Deodorization; The Value of Statistics.

Book II. treats of Military Hygiene, the conditions under which recruits are admitted to service, the conditions under which the soldier is placed, the effect of military service, foreign service, military and naval, from the British stand-point.

The American appendix to this volume is especially valuable as containing not only new material, but also matters peculiar to this side of the Atlantic. Due credit is given to Massachusetts for early and valuable work in the direction of Public Hygiene. The chapter on Water by Prof. E. Waller is quite full and complete. Professor Britten contributes a chapter on the Character and Distribution of American Soils. Dr. J. G. Richardson a valuable paper on the Climatology and Meteorology of the United States. Dr. D. F. Lincoln treats of Ventilation and Warming. E. S. Philbrick contributes a clear and concise paper on Removal of House-Waste, illustrated. The paper on Food Adulteration, by Prof. E. G. Love, is especially valuable for its abstract of the legislation of such States as have enacted adulteration laws up to the present year. The New York law is quoted in full.

Brief chapters follow on Disinfection, Vital Statistics, and Sanitary Inspection.

A Manual of Pathology. By JOSEPH COATS, M. D. Philadelphia: Henry C. Lea's Son & Co. 1883.

This manual was written with the idea of furnishing a work on pathology in English to replace that of Wilks and Moxon, which has become antiquated. It is well up to the times and presents the subject in a very readable manner. This is increased for the general practitioner by numerous allusions to the clinical bearing of the changes noticed. The importance which micro-organisms play in disease is recognized, and a due place is given to their consideration and illustration.

The work has not a great deal that is original beyond the illustrations, most of which were made especially for this work. The arrangement of the material is a very good one, and can be recommended to the student and practitioner as a good exponent of the modern condition of pathology, both general and special, in a volume of reasonable size.

— An aged Welsh Druid was recently tried for burning the body of his child, but was discharged on the ground that there was no law prohibiting it.

Medical and Surgical Journal.

THURSDAY, APRIL 24, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by Houghton, Mifflin and Company, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 Park Street, Boston, Mass.

REFORM OF MEDICAL SERVICE ON SHIPS.

Somewhat more than a year ago the British medical journals, as well as some of the daily newspapers, were vigorously agitating the question of the medical service on passenger vessels, largely incited thereto by the statements upon the existing conditions of Dr. J. A. Irwin, whose zeal and knowledge of the subject, resembling that of Mr. Plimsoll in regard to other marine abuses, enforced attention and carried conviction.

It was expected that a measure for the improvement of the medical service on all British vessels would have been introduced into the British Parliament by the president of the Board of Trade before this. The subject, however, is one of the utmost importance to American travelers and immigrants, and indirectly in periods of epidemics — as the recent one of small-pox — to the country at large, and it is very necessary that its proper regulation should be secured.

At the Cleveland meeting of the American Medical Association a committee was appointed to consider the regulation of emigration by Congress. This committee recently drew up a bill, which was presented to the national House of Representatives last month by General Slocum, and referred to the Committee on Commerce as an amendment to the Emigration Act of last year. The bill will be found in full on another page. Its passage and enforcement would reform many of the abuses which at present unquestionably exist, and tend to place the marine medical service — an extremely necessary department upon large passenger steamships — upon a positively and relatively useful and suitable footing, which at present is notoriously not the case.

The weak part of this bill is plainly the insufficient space prescribed for hospital accommodations. It may be that no more could be wrung from the cupidity of the owners of vessels, especially when it is at the same time demanded that the ship's surgeon, whose *maximum* pay has hitherto been only £9 or £10 per month and his position on a par with that of the chief steward or carpenter, should not only be provided with necessary assistants, but remunerated and treated as is the first officer or chief engineer,

It is said that competition between competing lines and dullness in trade and emigration have brought about a "cutting of rates" on ocean steamers similar to that with which we are familiar on our railroads. If so the present will prove both a difficult and desirable moment to introduce the proposed reforms.

We all recall the perfunctory and even fraudulent methods of complying with the laws for the vaccination of immigrants on some vessels of some steamship lines coming to this country, but when one becomes acquainted with the obstacles and want of facilities or support under which the surgeons of these vessels labored, a large part of the indignation, then only too justly aroused, should be transferred in many instances from the surgeon to his employer, the Steamship Company.

The great body of our citizens, whether those who travel or those who stay at home, have too direct and personal an interest in this reform of the medical service on ships to permit of its being dropped out of sight.

THE MEDICAL MAGNATES OF EDINBURGH.

During the earlier part of this century it was not uncommon for our medical graduates to finish their academic labors at the University of Edinburgh, which has just celebrated its tercentenary jubilee by conferring an honorary degree on Drs. Fordyce Barker and John S. Billings, beside a host of European celebrities. It is proper, therefore, to recall a few of the names that have made the University of Edinburgh illustrious in the annals of medicine and the kindred branches of learning. The University of Edinburgh, now one of the very largest in the world, and having more students than any other university except Paris, Berlin, and, perhaps, Vienna, was opened in 1583 as a town college created by and subject to the municipal council of the Scotch capital. The medical department of the University began in 1726, although a professor of botany had served since 1676, and Sir Robert Sibbard was not only appointed Professor of Physic in 1685, but received in the same year two unsalaried assistants. In 1706 Sibbard advertised in the *Edinburgh Courant* that he would teach natural history and the medical art *in privatis collegiis*, provided applicants could bring satisfactory testimonials as to their knowledge of Latin, Greek, mathematics, and philosophy. The Independent College of Surgeons, which had received a patent in 1695, caused a "Public Dissector of Anatomy" to be appointed in 1705.

But the medical department of the University owes its existence in part to the good sense of John Monro, a surgeon of King William's army, in part to four physicians — Sinclair, Rutherford, Plummer, and Innes — who, on their own petition, were appointed the Medical Faculty in 1726. The illustrious layman who helped nobly in this work was George Drummond, who founded the Royal Infirmary, opened in 1741. Meanwhile Alexander Monro had been appointed Professor of Anatomy in 1720, and may, perhaps, be called the father of the Edinburgh Medical School, because he made it famous by his Osteology, published in 1726, by his lectures, and by his son, who died in 1817 in the enjoyment of a European reputation

due in part to the folio volume of 1783, On the Structure and Functions of the Nervous System. The third Alexander Monro, likewise an anatomist, died in 1859, and had published his four volumes on the Anatomy of the Human Body in 1813. The next name, John Goodsir, brings us down to the present Professor of Anatomy, William Turner.

The Institutes of Medicine were taught first by Sinclair, who followed Boerhaave's Institutiones. Robert Whytt, professor from 1747 to 1766, was an advanced physiologist, but was surpassed by his successor, William Cullen, whose works are still quoted occasionally. James Gregory, an apostle of bloodletting, was succeeded by the two Duncans, of whom the elder taught from 1790 to 1819, and established a dispensary, an insane asylum, and the horticultural society of Edinburgh. His successors in office were, after his son, Alison, Thomson, John H. Bennett, and W. Rutherford, the present occupant of the chair.

The Practice of Physic has been taught by Rutherford, Gregory, Cullen, Home, Alison, and Thomas Laycock, who was partial to mental diseases. Midwifery was taught successively by Gibson (1726–1739), Robert Smith (1739–1756), Thomas Young (1756–1780), Alexander Hamilton (1780–1800), James Hamilton (1800–1839), Sir James Simpson (1840–1870), and his nephew, the present occupant. In 1847 Sir James Simpson professed himself less interested in having been appointed physician to the Queen than in having delivered a woman without pain while she was under the influence of ether. In the same year he discovered accidentally the modern use of chloroform, and soon after announced his discovery to the world, though some few persons thought it wrong to interfere with the curse of pain. Materia Medica used to be taught together with Botany, but was treated separately by Sir Robert Christison, who died two years ago, and was probably the most popular man ever connected with the University, among both teachers and students, beside being the head of the medical profession in Scotland. Christison is known to have finished his autobiography up to 1830.

The professorship of clinical surgery was held by James Russell from 1803 to 1833, and by James Syme from 1833 to 1869. Syme, it is needless to say, was the leading surgeon of his time and country, and one of the greatest of all Edinburgh professors. In 1818 he invented the waterproof "Mackintoshes," which the historian of the University, Sir Alexander Grant, thinks should be called "Symes." The same historian relates that Syme started a hospital of his own in the Minto House, where his assistant, Dr. John Brown, obtained the material for the famous tale, Rab and His Friends. Syme was succeeded by Joseph Lister, of antiseptic fame. Sir Charles Bell was Professor of Surgery from 1836 to 1842, Sir Wyville Thomson was Professor of Natural History from 1870 to 1882, and Joseph Black, Professor of Chemistry from 1766 to 1795, deserves a place by their side, as he was among the founders of quantitative chemistry. Finally it should be mentioned that Sir David Brewster was principal of the University from 1859 to 1868.

The medical department of the University of Edinburgh exceeds all others both as to professors and students, the latter numbering about 1800, or more than one half of all the students connected with the University. In 1826, the palmy year of the medical school, it had about 900 students; but it had only about 400 in 1840. The professors used to be appointed by the town council, with which they had many a brave fight. At present they are appointed by a board of seven curators. The medical department confers three degrees, — bachelors of medicine, masters in surgery, and doctors of medicine, the candidate for the latter alone being required to present a thesis on "some branch of medical knowledge, which he may have made a subject of study" after graduating as M. B. The Faculty is bound, also, to recognize extra-mural teaching over which the University has no control. In fact, the medical school of the University does not possess autonomy, and need not be consulted even in the appointment of new professors, unless those in authority so prefer.

EXTRAMURAL TEACHING IN EDINBURGH.

AT this time some details of the system of extramural teaching, which has largely contributed to make Edinburgh the medical centre it is, may prove interesting to many, especially as we chance to be in possession of such recently contributed by a well-informed correspondent.

In Edinburgh there is a large number of teachers, outnumbering even the professors, there being as many as two or three teachers of one subject, as midwifery, chemistry, or medicine, each lecturing independently of the other and in different rooms. These extramural lecturers or teachers set up for the most part under the auspices of the Royal College of Surgeons or the "School of Medicine" in Edinburgh. They may lecture without attendance on their lectures by a student being held as equivalent to attendance on the same class or subject intramurally or within the university. But it is almost the universal custom for each teacher to previously obtain the recognition of his status by the university, so that attendance on his lectures may count for the degree as equivalent to attendance on the same class within the university.

These lecturers for the most part give courses quite similar in character to those within the university, and therefore lecture, if one may so say, in opposition to the professors; and should a particular professor chance to be unpopular or a bad teacher, the extramural lecturer or lecturers may have a large class.

The fees charged by the extramural teachers are commonly one guinea less than the university fees (say £3 3s. instead of £4 4s.), but if it is desired by the student that his attendance on the extramural class should count for the university degree then he must pay to the extramural lecturer the same fee as he would have paid to the university professor, and the

fact of his having paid the larger fee must be noted on his card or certificate of attendance before it can be accepted by the university authorities. The Colleges of Physicians and Surgeons in Edinburgh grant licenses to practice, and it is largely in preparation for these that students attend the extramural lectures, and in such a case there is no restriction as to fee. Nor is there any restriction in the case of a university student if he has taken out the same class in the university and paid the usual fee, or has taken out the class at any other university.

Each extramural lecturer pays for his own rooms, provides his own apparatus, and holds all the fees he gets from his class. He is practically responsible to no one, but the university can always withdraw recognition of his lectures if they see a fit reason. When they grant recognition all they require is that the person has some status or standing in the subject on which he proposes to lecture, but recognition is often granted to comparatively young and inexperienced men; so much the worse for themselves if they are incompetent. A student for a university degree may only take out any four such extramural courses; all the others he must take in the university. This limits the effect of the opposition.

Besides these lecturers on the same subjects as university professors there are a few others who give courses on subjects not specially taught within the university, and not compulsory for the degree, as a course on diseases of the ear, eye, etc. Recently, however, a university lecturer on diseases of the eye has been appointed, as also one on insanity. These are the only two lecturers, not professors, holding their appointment direct from the university. In no case is the number attending the class limited. There are no small cliniques. Each of the clinical professors at the infirmary has a following of from twenty up to even eighty and one hundred. Men are drilled in the elements of practical diagnosis in groups of ten or twenty by the clinical tutor acting as assistant to the clinical professors.

The extramural teacher can lecture *when* and where he pleases, only he commonly finds it most convenient and profitable to lecture at the same hour as the professor of the same subject.

This system of extramural teachers is of great antiquity in Edinburgh, and has been found to supply a healthy stimulus to the university professors, many of whom came from the ranks of the extramural lecturers, especially in the practical subjects of medicine, surgery, and midwifery. A majority of the present professors were extramural lecturers before being appointed professors. The professor has always the advantage of endowment, better equipped and more commodious laboratories, and the chance of examining the student for his degree, which last induces men to stick to the university teachers.

In Glasgow a similar system has only recently been established, and there is now a very large number of extramural teachers there.

In Aberdeen the system or practice does not exist, and university professors are unopposed.

MEDICAL NOTES.

— Two more deaths from foot-ball are reported from England, both from injury to the spinal cord. In one case death was sudden; in the other the unfortunate young man lingered for four months in a hopeless state of paraplegia resulting from hæmorrhage into the cord.

— Mr. Lawson Tait recently read a paper on Relations of Ovulation to Menstruation before the Midland Medical Society, as we learn from the *Birmingham Medical Review*. He gave a historical sketch of the literature of the subject since 1843, the date of the publication of Dr. Ritchie's papers, and observed that although Ritchie's discoveries had been amply and frequently confirmed, the text-books still reiterated the mistaken view that menstruation was the equivalent of the œstrus or rut, and that it was due to the ovarian excitement of the ripened follicle. He next gave a series of observations derived from his surgical practice, in which it was shown that in forty-nine observations there was evidence of the concurrence of ovulation and menstruation in nine only, whereas in forty cases the evidence was either negatively (fifteen cases) or positively (twenty-five cases) against the ovulation theory of menstruation. It was therefore impossible to maintain a theory which was controverted by nearly eighty-two per cent. of evidence.

— The *London Practitioner* quotes a practice said to have been used for some time in the Milan Hospital for an aid to the diagnosis of fracture of the neck of the femur. The measure consists in exploring (whenever fracture of the neck of the femur is suspected) the short space between the trochanter and crest of the ilium. In place of considerable resistance, which is then produced in the sound limb through the tension of the tensor fasciæ latæ, there is found, when injury has occurred, a deep depression due evidently to the diminution of the tension of this muscle owing to the approximation of its points of attachment.

— A recent visitor to the venerable University of Pavia found among other relics of Scarpa, who is the special glory of that seat of learning, the head of the great anatomist with the soft parts entire preserved in a bottle. The fingers are also exhibited. Probably most such zealous devotees of science would be willing to occupy permanently a niche of a museum if they could thereby serve to illustrate any curious point of anatomy or of pathology. But it would seem more appropriate to most minds outside of relic-worshiping Italy, that if any remains of the old professor were to be made immortal, they should at least have combined a scientific with a personal value. His triangle would have been a more tasteful souvenir than his face.

— A curious pathological fact is related by M. Guillaume Chapus in a memoir, Sur les Médicins et la Médecine en Asie Centrale, which we find noticed in a French journal. One town of Turkestan, Kokane by name, is composed in great part of individuals afflicted either with goitre or cretinism. The traveler is struck with the appearance of the inhabitants, who

present all degrees of goitre from a slight fullness to enormous thyroid tumors. The peculiarity in the case consists in the fact that outside this one town goitre and cretinism are very rare. In Kokane the hygienic surroundings seem to be the most satisfactory. It is situated in a plain at an elevation of 1300 feet, and is abundantly supplied with pure water from a mountain stream. In 1878 the Russian troops occupied this town, and it was discovered that about a tenth part of the soldiers of the garrison became affected with goitre after a few months' stay. The tumors proved amenable to the external and subcutaneous use of iodine. It was considered prudent, however, to remove the garrison from Kokane, and another town of less pathological interest was selected as the political capital of the province.

— Pleuro-pneumonia has again caused alarm among cattle owners on Staten Island, and on the 10th of April four diseased cows were killed at Sailors' Snug Harbor. The authorities have quarantined the remainder of the herd where the disease appeared.

— A correspondent of one of our contemporaries, who gives painful evidence of being a scoffer, announces the discovery of a new germ which threatens us with a dangerous epidemic. He christens it the *bacillus lunaticus medicus*.

Correspondence.

PATHOLOGICAL CONDITIONS OF THE SKIN FOLLOWING THE INTERNAL USE OF BORAX.

MR. EDITOR, — Will you kindly allow me the use of your correspondence columns to request from any physician who may have observed squamous or other pathological conditions of the skin, following the internal administration of borax (whether for epilepsy or not), very brief notes of the cases for publication?

Treatises upon diseases of the skin do not appear to recognize such conditions, which have yet been observed in England by Gowers and also by other writers upon mental and nervous diseases, as well as here in Boston. Very truly yours,

EDWARD WIGGLESWORTH, M. D.

79 BOYLSTON STREET, *April* 19, 1884.

Miscellany.

DR. ALFRED STILLÉ ON THE VALUE OF ETHICAL CODES FOR PRACTITIONERS OF MEDICINE.

PROF. ALFRED STILLÉ delivered a valedictory address to the medical classes of the University of Pennsylvania on withdrawing from the chair of the Theory and Practice of Medicine, which is at once wise and graceful in an eminent degree.

We take the following extract, which we regret is all our space will permit, from the *Medical News* of April 19th. We think few dispassionate men can read it without giving an assent, however unwilling, to what Dr. Stillé says: —

It is sometimes asked why the medical profession alone should require a code of ethics for the regulation of its conduct. The question is not without the flavor of a sneer, and implies that there must be something peculiarly perverting in the science of medicine or corrupting in its practice which renders necessary so formal a statement of its moral duties. Let us consider the matter.

The moral government of mankind has never been intrusted to merely abstract propositions. The most ancient of moral codes, the Decalogue, maintains its authority unbroken by thousands of years. Their sum and substance are embodied in the two simple precepts of the founder of Christianity, and yet the former was expounded by Moses and his successors into an elaborate system of law, was adopted into Christianity, and thence by all the civilized nations of the world until it has interfused the legislation under which we live at the present day, and not the legislation only, but the usages of society in all ages. Wherever law reigned men who were similarly employed were drawn together into guilds and societies for the common benefit of their members, and in each statutes were enacted which enforced compliance with them by heavy penalties. Even among trades ethical rules existed, and when the learned professions were gathered into their respective colleges or faculties the privileges and rights of the members were counterbalanced by laws for the regulation of their conduct. The clergy alone were destitute of any specific ethical code, because they were held to be especially under the divine law from which all other codes emanated, and yet every religious community, of whatever denomination, possessed, and still possesses, special rules of conduct by which its members must be governed. The necessity of ethical codes arises from the fact, everywhere and always recognized, that either through lack of instruction, or through a defective or perverted moral sense, or through mere heedlessness, men do fail more or less to conform their conduct to justice and equity.

If men were habitually virtuous and just, unselfish and generous, if they could always see themselves as others see them, and judge their own motives and actions as strictly as they judge of other men's, then, indeed, there would be but little need for ethical or religious laws, for "they that are whole need not a physician." But law is nature's medicine for nature's defects and errors. Whoever imagines that he needs it not, that he possesses an inner light that will prevent his feet from straying into the paths of error, and enable him to decide justly in every conjuncture of life, is more to be wondered at for his boldness than admired for his modesty, for he lifts himself into a judgment seat where even Solomon did not dare to sit.

I have said that the relations of a physician to his brethren and to society differ widely from those of other professional men, and, indeed, of all other men whatever. The emulation and rivalry of clergymen and lawyers are, for the most part, displayed before the eyes of the world, so that there is no special opportunity for an evil-minded man of either profession to backbite or malign his brethren. Moreover, he knows that if he offends in this manner the court may affix a stigma to his name, or the religious body or the superior upon whom he depends may ruin him by an ecclesiastical condemnation. In the medical profession there is no tribunal which is under such imperative obligations to act or enforce its decisions so rigidly. Hence one necessity of a code of ethics. But another, already implied, is even more cogent. The physician is the only human being who is habitually admitted behind

the scenes of life's stage. He is the depository of secrets to which even a confessor's ear is a stranger, secrets on which station, honor, and life itself may depend, and even when not so burdened he is more than any one else the confidant and friend of those whose diseases he has healed. He is often the guardian of families that put their trust in him. Is it any wonder, therefore, that he should be jealous of the intrusion of a rival, or even of a friend, upon his preserves, and that, the evil of human nature aiding, the rival should endeavor to supplant him, and that thereout coldness, estrangement, animosity, evil-speaking, and ill-treatment should arise? Or is it surprising that the very confidential relations of a physician to his patient should expose him to the temptation to do wrong, and that he should, therefore, be warned by written laws of the danger he incurs?

These are the grounds out of which the ethical principles of the British and the code of the American medical profession grew, and which inspired the works of French and German writers on the same subject. They are the principles of honor, morality, and whatever is best in modern civilization, and, therefore, should be had in respect by all. It is a sign of decadence in the American social and medical systems that such laws are treated as obsolete or superfluous, and sneered at as fit only for children in leading-strings. Let me, as the parting counsel of one not without experience of life, adjure you to hold fast to this rock of safety, and, far from aiding to abrogate it, to strengthen and perpetuate it by every means in your power.

Impatience of authority and restraint has, perhaps, a deeper source than I have yet indicated. Its most conspicuous and violent outbreak occurred in France a century ago, and for a time covered the country with ruins steeped in blood. In our own day, the rebellion against law, if less sanguinary and destructive, is not less vehement, and is far more extended. Its name is Nihilism, and its creed is the denial of whatever has been known as religion, a hatred of all the virtues that are the fruit of faith, and a contempt of the obligations imposed by law. It tends to rob man of trust in whatever has been loved or respected in religion, in law, in the love and authority of parents, in the affection and obedience of children, in virtue, in duty, in honor, and in the established order of things that links the present to the past and to the future, making it the offspring of the one and the parent of the other.

If it were possible for this egoistic materialism to endure and prevail, the winter of humanity would indeed be near at hand, in which all signs of life, all progress and development, all beauty and nobility would be frozen out of it, and mankind would be reduced to a lower moral level than the beasts of the field. A world without faith! A world without love! As easy were it to conceive of a world without light or heat. In such a chaos what would become of all those institutions that have been established, perfected, and reverenced by advancing civilization? Conceive, for a moment, a community where no song of bell nor inward voice called to worship; where justice had become deaf as well as blind, because every man claimed to be a law unto himself; where there was no balm to soothe, no physician to cure, no right of property, no sacredness of person, where, in a word, mankind had lost whatever has hitherto distinguished humanity. If you can imagine such a herd of human beings — for it will no longer be a society or a community — you may behold in it a picture of the one that will assuredly arise if these nihilistic doctrines, this worship of self, this scorn of faith, this contempt of the past and exaltation of the present should prevail.

Let me plead with you to shun these poisonous principles which tend to the destruction of all that has been held noblest and best by the wise and good of every age; principles which put farther asunder the nations, communities, and individuals whom the physical improvements of the age should bind together and at last fuse into one. Faith is the parent and preserver of all good works. Unbelief, like Saturn, devours its own children. Faith is to man's nature what sunlight is to the world, clothing it with beauty and life; while unbelief is like the moon, in which the sun's rays create neither motion nor color, but fall forever upon its lifeless orb. Without faith, man's ambition is but narrow selfishness, contemptuous of the historic past on which it is compelled to build, and careless of what evil germs it may plant to be developed in the future. The higher a man rises in his humanity, the more clearly does he feel himself to be a link between the past and the future; the more fully recognize that what he has received that also must he transmit, increased, perfected, and consecrated by that spirit of love for humanity without which "good gifts wax poor."

ETHER ADMINISTERED BY THE RECTUM.

A NOTE on etherization per rectum, which, so far as we know, is quite a novel device, is published by Dr. Molière, senior surgeon of the Hôtel Dieu at Lyons, in *Lyon Médical* (March 30th). The idea was first suggested to the writer by Dr. Yverson, of Copenhagen, who, at the conclusion of a visit to the Lyons hospital, asked what anæsthetic was used there. To the answer, ether, he asked how it was administered, by mouth or by rectum. This question was the cause of the experiments detailed. The first operation in which this method was used was upon a young girl of twenty, and was for the removal of a tumor in the parotid region. The ether was insufflated to the bowel by an atomizer, giving a mixture of air and ether. No sign of anæsthesia appeared for ten minutes. The patient then declared she felt a strong taste of ether in the mouth, which was confirmed by the odor of her breath. She then began to sob and to talk incoherently. A few drops of ether were then held before the nose, and she almost instantly fell into a deep sleep. The operation was performed without the inconvenience of a respirator. On the removal of the rectal canula at the close of the operation the patient awaked. The quantity of ether absorbed had been very small.

In subsequent cases a rubber tube of the size of the finger was introduced into the rectum and connected with a flask of ether which was plunged into a vessel of water at 50° C. The ether boiled, and its vapor passed into the bowel. In the second of the cases described, in five minutes the signs of ether intoxication were present, but as the patient then got up the anæsthesia was completed by inhalation. In the third case, where a finger was to be removed, perfect anæsthesia was secured by the rectal administration of the drug. Auscultation revealed the passage of bubbles of ether in the intestine, and the odor of the drug was distinct in

the breath. At the most ten grammes of ether were used. No nausea or vomiting occurred.

As a result of the experience of Dr. Molière he concludes that this method of administration is likely to prove of great service. It suppresses, he claims, the period of excitement (this was especially noted in the case of a hard drinker, where experience teaches us usually to expect considerable excitement). It allows the quantity taken to be accurately measured, and reduces the amount necessary to a small quantity. It leaves the surgeon untrammeled by sponges and inhalers when operations are to be done on the face or mouth. It removes the disagreeable effects of inhaling the vapor. Further experiences of the method are promised us, and they will be awaited with interest.

PROBABLE TRANSFIXION OF THE HEART, WITH RECOVERY.

IN the *Edinburgh Medical Journal* (March, 1884) a case is reported of a woman with suicidal impulse, confined in an asylum, who was observed, just after getting into bed one night, to have become suddenly and violently ill, and medical aid was summoned at once. On its arrival she was found to be quite unconscious, very pale, skin cold and clammy, pupils widely dilated, but there was no conjugate deviation present; the features were drawn and altered, and the head was rolled rhythmically from side to side, patient moaning slightly at times. The radial pulse on the right side was very weak, that on the left almost imperceptible; rate 78 per minute. The left arm and leg were quite paralyzed so far as could be made out. The right arm was lifted and let fall feebly and aimlessly now and then. She had vomited a little, but no deleterious substance could be detected in the rejected matter by the rough examination possible at the time.

On palpation over the præcordia the cause of this rather puzzling condition was discovered. A knob about the size of a large pea was felt adhering to the chest wall, in the situation of the apex beat, and this proved to be the head of a large steel shawl-pin, about three and three eighths inches long, which the patient had succeeded in secreting, unobserved by the attendant in charge, and which she had thrust right into the chest, at the situation mentioned above, the part imbedded being directed slightly upwards and inwards, and measuring about two and three fourths inches. It was at once removed, and stimulants administered, and almost immediately the heart's action began to gain in force. The pulse became stronger and steadier, and consciousness slowly and gradually returned. For some time there was very urgent dyspnœa, and patient complained much of pain in the præcordia, but these unfavorable symptoms diminished as time went on, and after an hour had passed she was much better; the paralysis of the left side had disappeared; the pulse was steady, and of fair strength, rate 108 per minute, and she was quite conscious of what transpired around her. Four hours after the occurrence she was sick again, and vomited a little, but this soon passed off, and she fell asleep, and slept at intervals during the rest of the night, stimulants being given frequently in small doses. On the following day she complained of some pain at the site of puncture and of headache, but was otherwise pretty well, and her recovery after this proceeded without interruption.

The writer believes, from the point of puncture and the direction of the needle, that the heart was wounded near its apex. Reference is made to a similar case in Holmes's Surgery, and to another author who describes a tigress which lived for some time with seven lead bullets in her heart. The practical applications of these facts to the operation of cardiacentesis are of interest.

CARRIAGE OF PASSENGERS BY SEA.

IN the United States House of Representatives, March 24, 1884, Mr. Slocum introduced the following bill: —

A BILL TO REGULATE THE CARRIAGE OF PASSENGERS BY SEA.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That in every steamship or other vessel carrying or bringing passengers other than cabin passengers to the United States there shall be properly constructed and separated from other parts of the vessel two compartments or spaces to be used exclusively as hospitals, the one for the men and the other for the women, such hospitals to be located on the main deck or the deck immediately below it, and never on any lower deck, and to be in no case less in size than the proportion of eighteen clear superficial square feet for every fifty such passengers and crew; and such hospitals shall be supplied with proper beds, bedding, and utensils, and kept so supplied throughout the voyage.

SEC. 2. That every steamship or other vessel carrying or bringing passengers other than cabin passengers exceeding, with the crew, fifty in number, and less than six hundred, shall be required to carry a duly qualified, competent, and regularly licensed surgeon or medical practitioner, and where the number of such passengers and crew is over six hundred a junior or assistant surgeon or medical practitioner in addition, which surgeons or medical practitioners, junior and senior, shall be rated as such on the ship's articles, and shall be provided with surgical instruments, medical comforts, and medicines proper and necessary for diseases and injuries incident to a sea-voyage, and for the proper medical treatment of such passengers and crew during the voyage, and with such articles of food and nourishment as may be proper and necessary for preserving the health of infants and young children; and the services of such surgeons or medical practitioners shall be promptly given without fee in every case of sickness, disease, or accident to any of the passengers or crew, or to any infant or young child of any such passenger who may require their services; and the medical officer, where there is but one, and the senior where there are two, shall also be required to perform the duties of sanitary officers, to make daily inspections of all inhabitable portions of the vessel, and daily reports thereon in writing to the master of the steamship or passenger vessel, together with such suggestions and recommendations as in his judgment may be necessary to the preservation of health on board. He shall also exercise constant vigilance in regard to the condition of the provisions and water, and promptly report to the master anything which may appear to him to be deleterious to the health of any person on board.

SEC. 3. That for the proper exercise of these functions and the maintenance of the respect to which such medical and sanitary officers are entitled, they shall be provided with a steward or apothecary competent to dispense medicines under their direction and for their special service; and their tenure of office, remuneration, and right to suitable quarters, subsistence, and attendance shall be upon the same basis as and coördinate with the purser, first officer, and chief engineer of the vessel on which they serve.

SEC. 4. That for a violation of either of these provisions, or the disregard of the recommendations made in writing by the medical and sanitary officers as herein provided, the company to which the steamship or other passenger vessel belongs shall be liable to a penalty not exceeding two hundred and fifty dollars in every case.

ERRATA. — On page 157 of our present volume, number of February 14th, it should have been mentioned that the chamois leather bag devised by Dr. J. C. Warren as a substitute for strapping the testicle and for the treatment of hydrocele, of which a cut was given, could be obtained from Messrs. Leach & Greene, of Boston.

The JOURNAL in its issue for April 10th, page 358, inadvertently spoke of an address to the Massachusetts Legislature on Adulterated Drugs as having been signed by all the living ex-

presidents of the Massachusetts Medical Society. Besides the signers of this document two of the former presidents of the State Society are still in the enjoyment of life and the esteem of their several communities, — Dr. Samuel A. Fisk, of Northampton, president from 1870 to 1872, and Dr. William Cogswell, of Bradford, who served from 1876 to 1878.

REPORTED MORTALITY FOR THE WEEK ENDING APRIL 12, 1884.

Deaths reported 2547 (no reports from St. Louis, Buffalo, Milwaukee, and Providence): under five years of age, 920: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 334, consumption 426, lung diseases 321, diphtheria and croup 93, diarrhœal diseases 55, scarlet fever 38, measles 33, typhoid fever 33, whooping-cough 19, small-pox 14, cerebro-spinal meningitis 14, malarial fevers 13, erysipelas 11, puerperal fever 10, typhus fever one. From *measles*, New York 15, Baltimore eight, New Orleans four, Chicago three, Philadelphia two, Brooklyn one. From *typhoid fever*, Philadelphia nine, Boston four, Charleston three, Chicago, Baltimore, Cincinnati, and Pittsburg two each, New York, Brooklyn, District of Columbia, Nashville, Lowell, Lawrence, Acton, Chicopee, Spencer, and Marblehead one each. From *whooping-cough*, New York six, Chicago five, Baltimore two, Philadelphia, Brooklyn, Cincinnati, and Pittsburg one each. From *small-pox*, New Orleans 13, Nashville one. From *cerebro-spinal meningitis*, New York five, Philadelphia three, Chicago, Boston, New Orleans, Lowell, Worcester, and Quincy one each. From *malarial fevers*, New York four, New Orleans three, Chicago and Charleston two each, Boston and Cincinnati one each. From *erysipelas* Chicago three, New York, Philadelphia, Brooklyn, Boston, Baltimore, Cincinnati, New Orleans, and District of Columbia one each. From *puerperal fever*, Philadelphia three, Chicago two, New York, Brooklyn, Boston, Lowell, and Holyoke one each. From *typhus fever*, New York one.

Two cases of small-pox were reported in Cincinnati; scarlet fever 43, diphtheria 14, and typhoid fever two, in Boston.

In 100 cities and towns of Massachusetts, with an estimated population of 1,394,472 (estimated population of the State 1,955,104), the total death-rate for the week was 16.00 against 16.77 and 18.21 for the previous two weeks.

In the 28 great towns of England and Wales, with an estimated population of 8,762,354, for the week ending March 29th, the death-rate was 20.8. Deaths reported 3495: acute diseases of the respiratory organs (London) 359, whooping-cough 154, measles 135, scarlet fever 73, fever 41, diphtheria 20, small-pox (London 11, Liverpool and Sunderland two each, Birmingham and Newcastle one each) 17. The death-rates ranged from 12.5 in Derby to 30.7 in Halifax; Bradford 15.9; Birkenhead 17.8; Leicester 18.9; Sunderland 19.1; Sheffield 19.8; Nottingham 20.3; London 20.4; Birmingham 20.8; Leeds 21.5; Liverpool 22.2; Manchester 27.1. In Edinburgh 21.6; Glasgow 27.4; Dublin 27.2.

For the week ending March 29th, in the Swiss towns, there were 54 deaths from consumption, lung diseases 31, typhoid fever 37, diarrhœal diseases 11, diphtheria and croup 11, whooping-cough eight, scarlet fever one, erysipelas one. The death-rates were, at Geneva 31.6; Zurich 25.6; Basle 16.3; Berne 27.8.

The meteorological record for the week ending April 12th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM APRIL 12, 1884, TO APRIL 18, 1884.

BAILY, JOSEPH C, major and surgeon. Leave of absence extended three months. By paragraph 8, S. O. 83, A. G. O., April 10, 1884.

NEWTON, R. C., first lieutenant and assistant surgeon. Relieved from duty at Fort Sill, Indian Territory, and ordered to Fort Elliott, Texas, for duty. Paragraph 1, S. O. 77, headquarters Department of the Missouri, April 14, 1884.

PILCHER, JAMES E., first lieutenant and assistant surgeon. Assigned to duty at Camp Poplar River, Montana. Paragraph 2, S. O. 37, headquarters Department of Dakota, April 7, 1884.

CHAPIN, ALONZO R., first lieutenant and assistant surgeon. Relieved from duty at Fort Douglas, Utah, and ordered to Fort Laramie, Wyoming, for duty. Paragraph 2, S. O. 33, headquarters Department of the Platte, April 15, 1884.

WALES, PHILIP G., first lieutenant and assistant surgeon. Ordered to report to the commanding general, Department of the Columbia, for assignment to duty. Paragraph 11, S. O. 84, A. G. O., April 11, 1884.

LIST OF OFFICIAL CHANGES IN STATIONS OF MEDICAL OFFICERS UNITED STATES NAVY FOR WEEK ENDING APRIL 19, 1884.

WALES, P. S., medical director, to continue on duty as member of Ration Board.

WELLS, H. M., surgeon, to special duty at Hot Springs, Ark.

PECK, GEORGE, medical director, ordered as President of Board of Medical Officers detailed for special duty at Coaster's Island, near Newport, R. I.

GORGAS, A. C., medical director, WISE, I. C., surgeon, members of above Board.

NELSON, H. C., medical inspector, detached from Navy Yard, Washington, and placed on waiting orders.

MCMURTRIE, D., surgeon, ordered to duty at Navy Yard, Washington.

SUFFOLK DISTRICT MEDICAL SOCIETY. SPECIAL MEETING. — The *Section for Clinical Medicine, Pathology, and Hygiene* will meet at 19 Boylston Place, on Wednesday, April 30th, at 7.45 o'clock. Dr. H. J. Barnes will read a paper on Sewage Systems, and the Epuration of Sewage by Irrigation and Agriculture, with a description of this method of disposal of the sewage of cities as illustrated in Berlin, Paris, Danzig, Breslau, and other large towns.

ALBERT N. BLODGETT, M. D., *Secretary.*
ROBERT T. EDES, *Chairman.*

THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA holds its thirty-fifth annual session at Philadelphia, May 14, 15, and 16, 1884. Sessions from ten A. M. to five P. M., with intermission one P. M. to two P. M., at Annex to Union League, Broad Street below Chestnut. (Entrance on Moravian Street above Broad.)

APPOINTMENTS. — Dr. John H. McCollom has been reappointed City Physician of the City of Boston, and Dr. Arthur G. Griffin Port Physician for one year from the first Monday in May. The renomination by the Mayor of Dr. S. H. Durgin as member of the Boston Board of Health not having been confirmed by the Common Council Dr. Durgin retains office under the rules until an appointment is made.

Drs. W. W. Gannett and F. B. Harrington have been appointed Physicians to Out-Patients at the Massachusetts General Hospital.

Dr. Robert T. Edes has been nominated by the Medical Faculty of Harvard University to the chair of Clinical Medicine rendered vacant by the death of Dr. Calvin Ellis.

BOOKS AND PAMPHLETS RECEIVED. — Drugs and Medicines of North America. A Quarterly devoted to the Historical and Scientific Discussion of the Botany, Pharmacy, Chemistry, and Therapeutics of the Medicinal Plants of North America, etc. J. U. Lloyd. C. G. Lloyd, Cincinnati. 1884. Vol. I. No. 1.

Annual Report of the Librarian of Congress, exhibiting the Progress of the Library during the Year 1883. Washington. 1884.

A Comparison of Total and Manifest Hypermetropia as determined by the Prisoptometer, with and without the Use of Mydriatics. By H. Culbertson, M. D., Assistant Surgeon U. S. A. (retired). (Reprint.) 1884.

Seventieth Annual Report of the Trustees of the Massachusetts General Hospital and McLean Asylum, 1883. Boston. 1884.

Aneurism of the Femoral Artery and a Knife Wound of the Intestines. By W. O. Roberts, M. D. (Reprint.) Louisville, Ky. 1884.

Neurological Specialism. Presidential Address delivered at the Annual Meeting of the New York Neurological Society May 1, 1883. By W. J. Morton, M. D., New York. (Reprint.) 1883.

Transactions of the Rhode Island Medical Society. Vol. III. Part I. 1883. Providence. 1884.

Dictionnaire Annuel des Progrès des Sciences et Institutions Médicales. Par M. P. Garnier. Dix Neuvième Année, 1883. Paris: Germer Baillière et Cie. 1884.

Annuaire de Thérapeutique de Matière médicale de Pharmacie et d'Hygiène pour 1884 contenant le résumé des travaux thérapeutiques et hygiéniques publiés en 1883, etc. Par A. Bouchardat et par J. Bouchardat. 44e Année. Paris: Ancienne Libraire Germer Baillière et Cie. Félix Arean, Editeur.

Twelfth Annual Announcement of the American Medical College of St. Louis, 1884-85.

Seventeenth Annual Report of the Directors of the Massachusetts Infant Asylum. Presented to the Corporation at the Annual Meeting, April 8, 1884. Boston. 1884.

Peroxide of Hydrogen in Suppurative Conjunctivitis and Mastoid Abscesses, with a Report of two Cases. By A. E. Prince, M. D., of Jacksonville, Ill. (Reprint.) St. Louis, Mo. 1884.

TYPHLITIS AND PERITYPHLITIS.[1]

BY LEONARD WHEELER, M. D., WORCESTER, MASS.

I AM happy to be able to say that Hippocrates knew nothing about this matter of pericæcal abscess, nor did any of his successors for many centuries; happy because it is pleasant to come upon new ground now and then, and not be always reminded that we are merely recovering what shiftless intervening ancestors have forgotten. This subject we have somewhat cosily to ourselves, and all confined to the last half century.

French surgeons in 1825 to 1835 began to talk scientifically of inflammations in the right iliac fossa, but Dupuytren and his contemporaries failed to connect them with their commonest origin in disease of cæcum and appendix. A true understanding of the origin and course of these inflammations was first reached by Dr. Burne, of London, who, in 1836 and 1838, published two papers in vols. xx. and xxii. of the Medico-Chirurgical Transactions. In 1844 a model article on the subject was published in Copland's Dictionary of Medicine.

The methodical diagnosis and scientific surgical treatment of *pericæcal abscess* dates no further back than the prime of a man still living, Dr. Willard Parker, who, in 1867, published in the *New York Record* a paper upon the subject, in which he advocates free incision, even though there be no fluctuation, if the disease has existed over five days, and there be a reasonable suspicion from the symptoms of the case that pus has formed. Dr. Parker had, indeed, been anticipated by Mr. Henry Hancock, of London, who, in 1848, reported a case of perityphlitic abscess, and reasoned in much the same way in regard to treatment. The article was reprinted in the *American Journal of Medical Science*, but it was the report of only one case; it failed to establish any principle, and was forgotten. It was almost twenty years before Dr. Parker reached anew and independently the same point, and "employed successfully a method of treatment which may be said to have disarmed this disease of its terrors, and changed its issue from one almost invariably fatal to the reverse." This expression, which I have quoted from Dr. Gurdon Buck, is rather extravagant, for even before Dr. Parker's method came into use the fatality was probably not above fifty per cent. The next excellent paper was by Dr. Gurdon Buck, in the Transactions of the New York Academy of Medicine, 1874. He tabulates thirteen cases of operation, all successful. This paper was reprinted in 1876 along with two others by the same author in a pamphlet, to which was given the general title Abscesses in the Lower Abdominal Cavity and its Parietes. He dwells upon the anatomical arrangement of the fasciæ, which determine the direction of the migration of purulent matter in this region. The whole pamphlet is a valuable addition to the literature of the subject. In 1880 Dr. H. B. Sands published a paper in Annals of the Anatomical and Surgical Society of Brooklyn. He analyzes twenty-six cases, eleven of operation, of which one died. One other paper deserves mention as contributing to the development of the surgical treatment of these forms of abscess, namely, one by Dr. R. F. Noyes, of Providence, published in the Transactions of the Rhode Island Medical Society, 1882. Dr. Noyes tabulates one hundred cases of operation. The mortality was fifteen per cent.

Text-books are only just now beginning to incorporate the results of these studies. It is only in the very latest editions that a satisfactory treatment of the subject is found, such as Packard's Edition of Holmes, 1881, and the last edition of Gross, 1882. Dr. Sands, writing in 1880, says: "What is known about (perityphlitis) has not yet been embodied in the standard surgical text-books, but remains scattered among the pages of current medical literature." As to books on the practice of medicine, many of them, especially Ziemssen and Quain's Dictionary, contain excellent medical articles, but they do not indicate with sufficient clearness and emphasis where surgery should step in.

The following case lately turned my attention to the subject, and led me to select it for your discussion this evening: —

Mrs. H., aged thirty, mother of one child eight years old, called at my office January 8, 1883, complaining of a pain in right lower abdomen. In the summer of 1881 she had had a good deal of general abdominal discomfort and pain associated with constipation, and had slight and brief attacks of similar trouble since. More recently she had been under my care for a prolapsed and inflamed right ovary, and I at first associated the pain complained of with this. I made a careful examination, external and internal, and could find nothing to account for the pain. After a week she came again, and I found a small tumor in the right groin, which I thought an inflamed inguinal gland. It was small, superficial, not freely movable, and only slightly tender. There was pain in the inguinal region, but no considerable costiveness, no nausea, no marked fever, no deep tumor or extreme sensitiveness, and no fluctuation in the superficial tumor. February 1st, end of three weeks, during which the patient had been about until the last few days, fluctuation was distinct, skin becoming red, percussion flat. I opened the abscess by a small incision. An ounce of foul-smelling pus escaped, and a few bubbles of gas. Meanwhile, though the appetite had failed, there was no great pain, the temperature was only slightly raised, there had been no rigor, the bowels were only moderately constipated, not unusually so. There was nothing to excite any unusual apprehension except the bubbles of air, which made an intestinal perforation probable. February 13th the whole abscess cavity outside the abdominal muscles was laid open, and an opening through the fascia carefully sought with a probe, but none found. March 1st the spindle-formed cells of orange pulp (intestinal contents) were noticed in the discharge from the wound. April 13th a search with the probe still failed to discover the abdominal opening until the granulations in the bottom of the wound were scraped clean away, when an opening just about large enough to pass a silver probe was found above the middle of Poupart's ligament. Through this a somewhat devious sinus led to the cavity of the intestine one and one half or two inches away. A short time after this, air, and later fæcal matter, in small amount, began to pass with the urine. Later still a small amount of urine came through the wound. The amount of fæces or urine passing by the wound was never large enough to give much trouble, but the appetite failed entirely, the patient gradually wasted, and died of exhaustion ten months after the beginning of the trouble.

[1] Read before the Worcester Society for Medical Improvement.

The autopsy showed firm adhesion of the cæcum to the abdominal wall and iliac fossa by a thick mass of hard tissue. There were no adhesions to other parts of the intestine. A crooked sinus, one inch in length, passed from the abdominal wall through the thick mass of hard tissue mentioned above as binding the cæcum to the abdominal wall, and entered the cæcum through an opening one fourth inch in diameter. From this sinus a branch about two inches long communicated with the bladder. The colon just above the perforation was much contracted and thickened, while the mucous surface both above and below was studded with numerous small ulcers.

My explanation of the course of the disease in this case is that it began long before in an affection of the mucous coat of the cæcum, resulting in ulceration; adhesions were formed as the disease approached the serous surface. Then the connective tissue gradually thickened as the disease advanced, and hence the tough mass in which the cæcum was found imbedded, and by which it was firmly bound to the abdominal wall and iliac fossa. A passage was slowly made by ulceration through the abdominal fascia before any extensive accumulation of pus was made behind it. The sinus leading to the bladder must have been formed in part, if not wholly, after the external opening was made.

A little consideration of the anatomy of the parts involved helps to an understanding of the varied course of inflammations of this locality. The cæcum, two and one half inches long by two and one half inches wide, lies, with the appendix vermiformis and the beginning of the ascending colon, in the right iliac fossa, separated from the iliac bone on one side by the iliacus muscle, and from the vertebræ on the other by the psoas magnus. The appendix, from two to six inches long, is usually found at the end of the cæcum, interiorly and posteriorly, and curling upward and inward. The appendix is almost entirely covered with peritonæum. The cæcum and colon are covered anteriorly by peritonæum, but posteriorly are imbedded in connective tissue, which intervenes between the bowel and the iliac fascia. Now this iliac fascia is of the utmost importance, for, like all fasciæ, it serves to guide the migration of pus whether the abscess be above or under it. It is attached externally to the crest of the ilium as far forward as the anterior superior spinous process, and interiorly to the brim of the true pelvis. Below it helps to form the outer half of Poupart's ligament, and continues down the thigh as the fascia lata. Above it extends far upward over the psoas muscle quite to its attachments. The crural arch, which is spanned by Poupart's ligament, is divided into two parts by a prolongation downward to the bone, inserted into the ilio-pectineal eminence, and continued downward in the thigh as an intermuscular septum. The outer part of the arch gives passage to the muscles, the inner to the vessels.

An abscess may be formed over or under this fascia. If under, the pus will find its way along the psoas and iliacus muscles, and under the *outer* half of Poupart's ligament, and may best be evacuated by an incision of the fascia lata of the thigh. If the pus forms above the fascia iliaca, as in the diseases which we are considering, the pus creeps along between the fascia and the peritonæum, and is best evacuated by an incision through the abdominal fascia, and as soon as may be, lest in seeking its most eligible route it break through into the peritoneal cavity or bowel. If allowed to continue its course in the most eligible route, and it does not break through into the peritoneal cavity, owing to protective adhesions and thickening, it follows the iliac vessels, and emerges under the *inner* end of the crural arch, and into the inner side of the thigh. Bartholow states that it takes this direction in two thirds of the cases.

I have included typhlitis in my subject only because perityphlitis is inseparable from it. Any inflammation of the cæcum or appendix may result in an inflammation of the surrounding tissue, may eventuate in abscess. Though most cases of typhlitis get well without a perityphlitis, and many a perityphlitis advances no farther than a phlegmon and ends in resolution.

The most common cause of inflammation beginning in cæcum or appendix is a mechanical one. Some foreign body or a mass of hardened fæces remains long enough to irritate and inflame the mucous membrane. A mass of fæces impacted in the cæcum and colon may contain matters swallowed months before. A great variety of foreign substances have been reported in different cases as causes of ulceration or as the foundation of concretions, such as kernels of various grains, the stones or seeds of fruits, beans, a piece of bone or cartilage, a pin, nail, bristle, shot, gall-stones, inspissated mucus, a mass of ascarides' eggs, a bundle of lumbricoid worms. An idiopathic catarrh may occur here, as in other mucous tracts. Disease may arise from injury or follow certain constitutional diseases, as typhoid or tuberculosis. Disease of the cæcal mucous membrane arising from either of these causes may be slight and transient or severe in any degree, though probably not fatal except indirectly by perforation of the bowel. The lighter, simply catarrhal cases of typhlitis are more common in children. The severe cases of ulcerative inflammation are more apt to be met with in adult life, and it is an important fact in connection with them that they are very liable to relapse. Cases are recorded by more than one author of a dozen relapses in the same individual.

I shall say a few words in regard to symptoms, diagnosis, prognosis, and treatment, not attempting to speak fully of either.

Symptoms. An attack of typhlitis is more common in young males. It is usually abrupt, though often preceded by an irregularity of the bowels. At the time of the attack the bowels are usually constipated. Pain and tenderness are complained of in the right inguinal region, there is slight fever and probably vomiting, and the attack may pass off with no greater trouble than this. Such cases are considered common, and are often repeated in the same individual. I have never come across one, however, or if I have, have not recognized it. The attack may be something more severe than this, a tumor be demonstrable, the right leg drawn up, and the decubitus on the right side in order to diminish pressure on the diseased part. The great majority of *such* cases even recover without the formation of abscess or development of peritonitis after a duration of from three or four to ten or twelve days, though an induration may remain for months.

Perityphlitis by no means necessarily implies abscess. The symptoms of the most formidable cases are similar to the above except in degree until perforation occurs or an abscess forms. A perforation into the peritoneal cavity makes itself very promptly known by the symptoms of acute general peritonitis. A perforation into the post-cæcal cellular tissue is not so mani-

fest, nor is it easy to know when suppuration begins.

Diagnosis. The number of diseases with which typhlitis and perityphlitis may be confused is large, but in most cases it only seems necessary to have the disease in mind in order to discover it. Mr. Maunder, of London, was called to tap an ovarian cyst, and found a cæcal abscess. Dr. Fordyce Barker narrates two cases, both seen by eminent counsel. The first patient was the wife of a physician, who proved to have a pelvic hæmatocele, although the diagnosis had been perforation of the appendix. The second was daughter of a physician, who proved to have a perforation of the appendix when the diagnosis had been pelvic hæmatocele.

Prognosis. The prognosis in typhlitis in which no perforation occurs is good. The patients almost invariably recover. When there is a perityphlitis not suppurating the danger is from recurrences, in which suppuration may take place. Dr. Wm. Pepper has a paper in the Transactions of the Pennsylvania Medical Society for 1883, in which he lays particular stress upon this liability to recurrence, and gives one case of twelve relapses. If the disease goes on to perforation, then the result depends in great measure upon the course taken by the pus and the surgical means employed. A perforation through any part covered by peritonæum, including thus nearly all perforations of the appendix, is a desperately fatal accident. It is possible that adhesions precede the perforation, so that an opening is made directly or through the medium of an intraperitoneal abscess into one of the hollow viscera or through the abdominal wall. If a perityphlitic abscess forms, the most favorable course for the pus is through the cæcum or rectum. Perforation through the abdominal wall is not so favorable. Of twenty-eight cases collected by Dr. Bull, of New York, eleven were fatal.

Treatment. In non-perforative cases, if there is much pain and tenderness, opium is proper until there is less, then small doses of saline laxative guarded by a small opiate, for it is desirable to relieve the cæcum of contents, both for the sake of diagnosis (to exclude impaction) and to relieve the patient of pain caused by the distended gut. At the same time externally a poultice, ice, or counter-irritation, may be used. Calomel is used by English practitioners generally, and is now and then mentioned by Americans. If an abscess has formed it is to be evacuated immediately, and if there is a reasonable belief that pus is present, although no fluctuation is found, the surgeon is justified in or is required to test the belief by aspiration or incision. Upon the point of the diagnosis of pus Dr. Sands writes: "Rigor, sweating, high temperature, acceleration of pulse, abdominal pain and tympanitis, and an increasing extent combined with diminishing firmness of the abdominal tumor are the chief signs which indicate the formation of pus. But none of these signs is invariably present, and it would be a difficult matter to say which one of them is the most important. But although in the early stages of the disease it may be impossible to discriminate between the cases that are going to terminate by resolution and those that are to end in suppuration, the latter may usually be distinguished toward the close of the second week by the general unfavorable condition of the patient, who seems to be growing worse instead of better; whereas when resolution is about to take place, the later course of the disease is comparatively mild and favorable." The smallest aspirator needle may be freely used to decide the diagnosis. The operation is done by making an incision parallel with Poupart's ligament through the successive layers of the abdominal wall until the fascia transversalis is reached; the pus is then sought by the needle if fluctuation is not present, and the abscess then opened sufficiently to allow the entrance of a finger to explore the cavity for foreign bodies. Fæcal odor and the presence of bubbles of gas in the abscess do not prove the existence of a perforation of the intestine, though making it very probable. It is well to be aware that a perityphlitic abscess may be quite behind the colon and extending far upward toward the liver. In such case it would have to be approached from the side. Dr. Noyes, of Providence, has tabulated one hundred cases of this operation. The mortality was fifteen per cent. In Dr. Bull's sixty-seven cases of abscess tabulated in 1872, before the operation came much into use, the mortality was forty-seven per cent.

In cases of perforation into the peritoneal cavity it has been proposed to make an abdominal section, clean out the cavity, and stitch the opening to the abdominal wound. But the difficulty of diagnosis is too great to allow of spending much hope upon this idea.

CRITICISMS, FROM A CHEMICAL POINT OF VIEW, ON SOME FAVORITE PRESCRIPTIONS.[1]

BY HENRY LEFFMANN, M. D.

The few points that I present to the College this evening will include little that is absolutely new, but I think the time will not be entirely wasted, as I know that the prescription list of most of our drug stores will give numerous examples of the violation of chemical principles here mentioned. My attention was called to this topic by my being shown by an apothecary a prescription calling for syr. hypophosph., tinc. ferri chlor., acid. phosp. dil., concerning which he said that in the proportions ordered he could never make the mixture up clear. I examined the precipitate, and found in it, as I had expected, a large proportion of the iron and other basic ingredients. This is a simple case of incompatibility. Turning the matter over in my mind, it has seemed to me that while some attention is paid to cautioning students as to the general nature of incompatibility, very little or none is given, especially in the shallow chemical teaching of many medical schools, to the properties and qualities of chemical substances in their relations to the animal tissues and the manner of administration. I present here, therefore, a brief consideration of a few well-known remedies.

Under the name of *colorless tincture of iodine* several preparations are used, depending for their popularity on the fact that they do not stain the skin. They are prepared either by the use of ammonia or of sodium sulphite or hyposulphite. They owe their particular property, or rather absence of property, to the neutralization of the iodine, and just to the extent that the iodine is decolorized is it to the same extent deprived of virtue. The free active affinity of the iodine, to which its local action must be due, is destroyed in these preparations, and the destruction is not slow or uncertain, but in two of the methods

[1] Read before the College of Physicians of Philadelphia, April 2, 1884.

mentioned it is sufficiently rapid and definite to be made the basis of a method of quantitative analysis. It is certainly difficult to see how any person could go so wide of simple chemical principles as to invent or employ this mixture.

Potassium chlorate, or, as it is still erroneously called by many, chlorate of potash, is a remedy concerning which extraordinary claims have been made, based upon most erroneous notions of its chemical qualities. It is employed in the laboratory as a source of oxygen. Knowledge of this fact has led to its employment as an oxidizing agent in diseases which have been supposed to express deficient oxidation. I have nothing to say here as to the clinical results obtained from potassium chlorate in any disease, — although I believe it is much less in favor than formerly, — but I enter a protest against any advocacy of its usefulness as an oxidizing agent. Under temperatures and conditions such as those which it meets in the human system it is one of the most stable of bodies, does not part with its oxygen or chlorine, and, indeed, will not begin to do so except under very high heat. I have found by actual experiment that ten grains of the salt kept for two hours at a temperature of 100° F. in contact with an artificial gastric juice did not develop oxidizing qualities sufficient to oxidize one sixtieth of a grain of phosphorus. This experiment is merely confirmatory of what everyday experience with the substance teaches.

Potassium permanganate has been more or less in favor with physicians for a score of years. It is well known as an oxidizing agent, its powers in this respect are well marked. It is as little suitable for internal administration for such purpose as the body just considered, but for an opposite reason. Its chemical properties are developed by almost every substance, and in the doses in which it is given it will be decomposed and rendered inert very shortly after being swallowed. Within a very recent period the salt has come into notice as a remedy for amenorrhœa, and great has been the tribulation of apothecaries. It has been given in pill form, and all the usual excipients have been unavailable. I have made a few tests of the permanganate pills now in the market, and I find with regard to those made by one of the most reliable houses in this city that the permanganate is all decomposed and converted into the insoluble manganese dioxide. The preparations of two other manufacturers made up with some mineral excipient, probably kaolin, were in good condition, but as soon as placed in a mixture of hydrochloric acid and pepsine they begin to decompose into insoluble manganese oxide. These pills vary in strength from one eighth to one grain. This small quantity of permanganate certainly must soon decompose in the stomach, and the only virtue which it can have is from the manganese itself, and if this is effective common sense would seem to suggest that the result could be best obtained by exhibiting some definite compound of manganese, such as the chloride or sulphate. When we consider the chemical relations of the salt, and almost certain inertness of it in small doses, the gravity with weich the learned English therapeutists, who recommended it in amenorrhœa, have discussed the possibility of its producing abortion, becomes almost burlesque. I do not desire, of course, to impugn the clinical observations that have been recorded on this point, but I feel obliged to say that if the insoluble and variable decomposition products of one eighth of a grain of potassium permanganate can affect the function of any one organ, then the difference between us and the apostles of the infinitesimal is small indeed.

I cannot dismiss these two compounds, which owe their popularity to mistaken notions of their properties, without saying a word or two as to the exhibition of oxidizing agents. If rational therapeutics or physiological study indicates remedies of the so-called oxidizing class, then it will be found that no better agents are known to us than those which have long been in our hands. In nitric acid, nitro-muriatic acid, and chlorinated soda we have substances which are sufficiently stable to resist the organic bodies of the saliva and gastric juice, and are sufficiently active to give oxidizing effects if such (other than local action) can be obtained. I have grave doubts whether the nutritious fluids of the body can be oxidized by any method, but there can be no doubt whatever that such effect cannot be attained by either a body — potassium chlorate — which yields its oxygen only at a red heat, nor by one — permanganate — that decomposes the moment it touches any form of organic matter. Some years since a correspondent in one of our medical journals gravely recommended the use of raspberry syrup to disguise the taste of potassium permanganate. It was of course entirely successful, the taste was destroyed, so was the compound.

Caffeine citrate is a remedy much in favor, and is a remarkable instance of how much physicians take for granted in the remedies they use. There is no caffeine citrate in the market, and it is doubtful whether any such a salt can be prepared. The commercial preparations are either pure caffeine or variable mixtures of it with citric acid.

The manufacturers in this city each furnish a different article, except in cases in which they buy from a common source; and a house in a neighboring city furnishes an article which contains no citric acid. Some of the samples are purely bitter in taste, while others are distinctly sour. Analyses of some of the commercial salts are recorded in a paper read before the last meeting of the American Pharmaceutical Association by Dr. G. C. Wheeler. He found the quantities of caffeine varied from 96.5 per cent. to 63.5 per cent.; of citric acid from 63.5 per cent. to 3.5 per cent.; none of these figures correspond with the proportion of a true citrate.

It seems to me that accurate clinical observation cannot be made with a preparation of so uncertain a character; for, as seen by these figures, the proportion of active ingredient may vary thirty-three per cent., and the lesson that these analyses teach us is that when the effects of caffeine are wanted they are best obtained by the use of the pure alkaloid, and not by a pretended and uncertain compound of it.

HISTORY OF A CASE OF PERIHEPATIC ABSCESS.[1]

BY EDWARD T. BRUEN, M. D.,

Physician to the Philadelphia Hospital, Demonstrator of Clinical Medicine in the University of Pennsylvania.

The accompanying specimen exhibits an abscess which has occurred between the diaphragm and the liver. The abscess contained nearly a pint of laudable pus. The superior wall of the abscess was the

[1] Read before the College of Physicians of Philadelphia, April 2, 1884.

diaphragm, and the inferior the perihepatic capsule; the hepatic substance was not involved; indeed, the liver was normal. There were evidences of catarrhal inflammation in the colon, and one or two nearly cicatrized ulcers. The only other lesion in the body was found in the right pleural cavity, the lower portion of which was obliterated by inflammatory adhesions.

The clinical diagnosis presented some interesting features.

The patient, a young man aged twenty-eight, was admitted to the Philadelphia Hospital November 30, 1883. His previous history indicated that he had suffered from an attack of dysenteric diarrhœa four weeks before his admission, although he had convalesced from this attack. He was evidently much emaciated. The temperature until December 8th ranged from 100° F. to 102° F.; from December 14th, from 99° F. to 101° F., after which it never rose above 99⅘° F. in the evening, and was always 98° F. in the morning; this continued until the fatal termination of the case on the 20th instant. The pulse was usually above 100. There was occasional sweating; no chills. Extreme tenderness was felt over the hepatic region, associated with pain during the first ten days, the hepatic dullness extending four inches in the nipple line, and about five inches in the axillary region. Physical examination of the chest upon the right side revealed the evidences of a dry pleurisy; there was some cough, which was dry and hard, but not very annoying. Appetite and digestion were fairly good. Urine normal.

The diagnosis of hepatic abscess was made during the first week, chiefly because the symptoms of hepatic lesion, already detailed, were antedated by dysenteric diarrhœa. The pleural lesion was regarded as a secondary inflammatory process engendered by hepatic disease. On December 10th all symptoms of pain and tenderness had vanished; the patient's strength, appetite, and general condition markedly improved; the temperature had fallen to 99° F., so that the diagnosis was revised to that of perihepatitis. From December 10th the improvement continued until the 20th, when, after an attack of vomiting, the patient suddenly died.

The autopsy appeared to prove that the inflammation which resulted in the formation of the abscess was primary in the pleura, and the secondary irritation developed the local peritoneal process.

The symptoms of abscess in the hepatic substance are frequently latent. I recall one instance of a patient admitted October 9, 1877, who walked to the hospital and remained under treatment until the 15th, suffering from apparent remittent fever. The day of his death he rose, in the absence of the nurse, and walked down-stairs to smoke a pipe; that afternoon he had a hæmorrhage from the bowels, and died. The temperature of this patient was between 99° F. and 101° F., and the clinical diagnosis was remittent fever, or typhoid of the variety called ambulatorius. The autopsy revealed an abscess about the size of a fœtal head occupying the convexity of the right lobe of the liver.

In the case I have reported this evening the subsidence of pain and tenderness, and the temporary improvement of the patient, certainly misled me. Under similar circumstances I should certainly introduce an aspirator, as I was inclined to do in the beginning of this case, because I am satisfied that the healthy liver can be punctured by a fine needle without damage, whereas either a hepatic or perihepatic abscess may at any time prove fatal by rupture.

Finally, if my explanation of the ætiology of this abscess is correct, the case is interesting as showing the relation of pleurisy to serious perihepatitis.

REPORT ON DERMATOLOGY.

BY GEORGE H. TILDEN, M. D.

PEMPHIGUS.

The opinion of Hebra that acute pemphigus did not occur is no longer accepted as correct, many isolated instances as well as epidemics [1] of the acute form of the disease having been observed. Riehl [2] reports an interesting case in this connection. The patient, a boy fourteen days old, first presented, on the sixth day after birth, a tensely-filled bulla upon the neck, in a region which, the day before, was erythematous. Shortly afterward appeared upon the face and back, and later upon the arms, a number of fresh bullæ. When seen at the hospital the moderately well-nourished child showed upon the forehead, cheeks, and lower extremities irregularly disposed bullæ of sizes varying from that of a pea to that of a dove's egg, most of which were filled with a clear, yellow fluid, while in several the fluid was already opaque. The epidermis covering these bullæ was very thin, and gave way at the slightest insult, in consequence of which many of the lesions were in a collapsed condition, the mixture of epidermis and fluid contents forming yellowish crusts. The side of the neck and the anterior surface of the thorax and abdomen presented the appearance of a burn of the second degree, so thickly were the bullæ crowded together, almost the whole extent of epidermis in these regions being separated from its bed. The outer edge of this confluent mass of bullæ was irregularly crescentic in form, and was marked by a narrow red halo, which separated it from healthy skin. The isolated bullæ were also surrounded by erythema. There was no spontaneous pain, but the excoriated regions of the body were very sensitive to the touch. The child's urine contained no albumen, its bodily temperature remained normal, and examination of the internal organs gave no evidence of disease. The general condition of the infant was fair, and it took its nourishment regularly, although suffering for several days from diarrhœa of greenish, semi-fluid stools. Besides the general eruption of pemphigus there was a certain amount of eczema intertrigo in the groins, and in the mouth aphthous spots of moderate extent. The mother was perfectly healthy, and there was no evidence of syphilis in either parent, while a former child, already sixteen months of age, had always been in good health.

The treatment consisted in the application to the eczematous regions of starch powder, and to the rest of the body of a mixture of olive oil and lime-water, while at the same time attention was given to the state of the bowels. The child was entirely well in about three weeks, the most prominent symptom, namely, the formation of bullæ, lasting in all about two weeks. The defect in the epidermis caused by an individual bulla was repaired in about a week, and there re-

[1] Bohn Hautkrankheiten, page 191, supplement to Gehrhardt's Handbuch der Kinderkrankheiten, and Ziemssen's Handbuch der sp. Path. und Therap., Band xiv., page 537.

[2] Wiener med. Wochenschrift, No. 51, 1883.

mained behind merely slight redness and subsequent yellowish pigmentation of the affected regions of the skin.

The contents of the freshly-formed bullæ was of neutral reaction, coagulated rapidly upon exposure to the atmosphere, and upon microscopic examination showed the presence of nothing but epidermal detritus and leucocytes. The covering of the bullæ was found to be made up of the horny layer of the epidermis and of the cells of the granular layer, together with a slight admixture of white blood corpuscles. In each one of the twenty specimens examined were found quantities of a vegetable micro-organism consisting of various sized and irregularly shaped groups of conidia or spores. These collections of spores were situated between the layers of epidermis, and accumulated, as a rule, about the openings of the cutaneous follicles. The hair follicles and the excretory ducts of the sweat glands were not unfrequently found to be stuffed full of conidia. Bands of mycelium were also present, but in very small amount, being either isolated or inclosed in groups of spores. These micro-organisms resembled very much in appearance those found in tinea trichophytina, but the amount of mycelium present was very much less than in this disease, and the grouping of the spores was more like what one finds in tinea versicolor.

In the writer's opinion the constant presence in large quantities of these micro-organisms, taken together with the fact of their situation inside of the hair follicles and ducts of the sweat glands, is evidence against their accidental admixture with the specimens examined, and is sufficient to justify the assumption of their being the ætiological factor in the production of the cutaneous lesions. That the presence of such micro-organisms in the delicate skin of infants is competent to cause the formation of bullæ is demonstrated by an instance mentioned by Riehl, in which the ordinary lesions of tinea trichophytina corporis upon an infant six months of age developed subsequently into a bullous eruption resembling in appearance pemphigus serpiginosus. Such ætiology would account for the appearance of acute infantile pemphigus in epidemics, and justifies the opinion of Olshausen and others that the disease is an infectious one. The afrebrile course of the malady, moreover, and the comparatively slight influence which it has upon the general condition of the affected children goes to show that the cutaneous lesions in such cases are due to some cause the influence of which is confined to the skin.

Dr. P. Mayer [1] publishes a case of fatal pemphigoid dermatitis. The patient, a man, sixty-five years of age, was first attacked by an eczematous eruption upon the body, which was attended by intense itching. Four weeks afterward there began to appear upon the trunk and lower extremities irregularly distributed bullæ, while at the same time ominous symptoms of general disturbance showed themselves, consisting in loss of appetite, sleeplessness, and fever, together with rapid failure in strength. The cutaneous lesions increased in extent, and developed into ulcerations with diphtheritic exudation. Death took place in the seventh week from the beginning of the malady.

At the autopsy, with the exception of nodules of broncho-pneumonia, there was nothing abnormal found in the internal organs. Microscopic examination of the skin, however, showed the existence of widely-spread endo-arteritis of the cutaneous blood-vessels, causing obliteration of their calibre. Many of the cutaneous nerve fibres in the unaffected as well as in the diseased regions of the body were found to be in the early stage of parenchymatous degeneration. The motor nerves and the nerves of the sympathetic system were unaffected, as were also the roots and ganglia of the spinal nerves. The spinal cord itself, however, upon microscopic examination showed evidence of pathological changes, consisting in grayish bands running along the posterior fissure of the cord throughout the whole of the cervical and dorsal regions. Similar appearances were also to be seen in the posterior columns of the upper dorsal region, and in the lateral columns of the lower dorsal and the lumbar regions were translucent patches. The microscope showed in all these situations thickening of the interstitial tissues, and the occasional formation of bands of sclerotic connective tissue, as a rule following the course of the blood-vessels, which themselves presented thickened walls, and, in consequence thereof, partially obliterated lumen. The anterior columns of the cord were entirely normal in appearance.

The author refers to the recent works of Leloir and Schwimmer concerning the neuro-pathogenesis of cutaneous disease, and is of the opinion that at present (thus far) all that is proven in such cases is coincidence between affections of the spinal cord and synchronous disease of the skin. Concerning the case published by himself, he draws attention to the coincident and extensive obliteration of the calibre of the blood-vessels in both the spinal cord and skin, and concludes that by reason of such changes in the blood-vessels there ensued disturbances of nutrition in both of these organs. In the spinal cord, as is often seen, such nutritive disturbances resulted in sclerosis of the interstitial tissue, and in consequent degeneration of nerve tissue. In the skin, on the other hand, there was produced trophic disturbance sufficient to cause the cutaneous pathological process, already set up by changes in the central nervous system, to assume unusual severity, and thereby destroy the life of the patient.

Another case of acute and fatal pemphigus in an adult is published by Dr. Danek.[2] The patient was a healthy man, twenty-two years of age, with good family history, and presenting no evidence of syphilis. He was first attacked by a chill, which was followed by fever, and was seen in the hospital two days afterward. He was well nourished, but the mucous membranes were somewhat pale. The neck, chest, both front and back, the arms, and, to a less degree, the belly and lower extremities, were covered with numerous bullæ of sizes varying from that of a pea to that of a hazelnut, which were filled with a clear, yellow fluid, and situated singly and in groups upon an erythematous base. There was no evidence of disease of any of the internal organs, and there was no albumen in the urine. Fever, however, was present, the evening temperature being as high as 39.4° C. The bullæ increased in size and number, and coalesced to such a degree that in ten days' time the body was almost covered by them, and large regions of skin were deprived of epidermis. At the same time bullæ of smaller size began to appear upon the mucous membrane of the lips and mouth, and the general condition of the patient became rapidly worse, with increase of fever, and the appearance of albumen in the urine. Shortly before death,

[1] Virchow's Archiv, Band xciv., Heft 2.

[2] Wiener med. Wochenschrift, No. 36, 1883.

which took place in three weeks from the beginning of the disease, the body presented the appearance of a burn with widely spread cutaneous suppuration, accompanied by continual high fever, diarrhœa, and delirium. At the autopsy, with the exception of hypostatic pneumonia in the base of each lung, there was nothing abnormal to be detected in any of the internal organs. The spinal cord also presented upon careful examination no pathological changes. The peripherical nervous system and the skin were not examined microscopically.

HERPES ZOSTER.

The case of a woman seventy-six years of age, who died in hospital after having had an attack of herpes zoster intercostalis dexter, affords to Dr. Lesser[1] the opportunity for the discussion of the above subject. The eruption commenced between the spinous processes of the second and third dorsal vertebræ and extending forwards over the right breast finished at the point of attachment to the sternum, of the cartilage of the fifth rib. The eruption consisted of the usual vesicular and pustular lesions of herpes zoster and of superficial ulcerations caused by the coalition and breaking down of the same. The region of skin affected was that supplied by the fifth and partially by the fourth pair of intercostal nerves. The patient died some three months after the beginning of the cutaneous manifestations, which at the time of death were entirely healed with the formation of superficial cicatrices.

At the autopsy the fourth, fifth, sixth, and seventh intercostal nerves were dissected out from their point of exit from the foramina intervertebralia as far as the axilla. The sixth and seventh nerves were entirely normal. The fifth nerve was notably thinned, flattened, and of a reddish-gray translucent color. Similar but much less marked changes were to be seen in the fourth nerve. The spinal ganglia corresponding to the above nerves and the fourth sympathetic ganglion were subjected to microscopic examination. The sixth spinal and the fourth sympathetic ganglia were normal, while the fifth spinal ganglion presented marked pathological changes. The upper half, which was darker than normal, showed absence of almost all nerve tissue, this being replaced by connective tissue which was united with the connective tissue envelope of the ganglion, which itself was much thickened. At the line of junction between the normal and pathological regions the blood-vessels were notably dilated. The small amount of nerve tissue recognized as present in the upper half of the ganglion was mostly in a condition of granular degeneration. The lower half of the ganglion presented the normal condition of things, namely, a fine net-work of cellular connective tissue, containing strongly pigmented ganglion nerve cells and bundles of nerve fibres. Microscopic examination of the fifth nerve itself showed granular degeneration of numerous nerve fibres. The fourth spinal ganglion showed changes similar to those found in the fifth ganglion, while the fourth intercostal nerve on the other hand was entirely normal in appearance.

As cause, therefore, of the cutaneous lesions in the above case may be assumed the formation of cicatricial tissue and consequent destruction of nerve tissue in the fourth and fifth spinal ganglia and secondary degeneration of the fifth intercostal nerve. The ætiological factor in the production of herpes zoster is in the majority of cases pathological change in the spinal ganglia or in the Casserian ganglion, in some instances changes also in the peripherical nerves, and in very rare instances disease of the central nervous system. Of fourteen autopsies in cases of herpes zoster known to the author, in eleven there was undoubted disease of the spinal ganglia corresponding to the nerve supply of the regions of skin involved by the eruption, in one case a neuritis, in one instance pathological changes in the corresponding posterior spinal root, and in another cicatricial contraction in the origin of the trigeminus and probable remains of inflammatory processes in the Casserian ganglion.

As to the manner in which such changes in the nervous system give rise to the cutaneous manifestations of herpes zoster there are three hypotheses: —

(1.) The opinion of Friedreich that the eruption is due to a progressive neuritis which starts from the ganglion involved and finally reaches the ends of the cutaneous nerves, and in this way gives rise to the pathological changes in the skin. The fact, however, that cases of herpes zoster are almost never attended by motor disturbances, although the motor and sensory nerve fibres join immediately beyond the ganglion to be intimately united throughout the whole of their course, is evidence against the correctness of this opinion. In typical inflammations of the peripherical nerves, motor disturbances consisting in motor irritability, paralysis, and muscular atrophy are common symptoms. It was the fact that motor disturbances are so uncommon in cases of herpes zoster which led V. Bärensprung to seek for the cause of the disease in the posterior spinal ganglia. The small number of cases of herpes zoster in which motor disturbances are observed are dependent upon peripherical neuritis, and not upon disease of the spinal ganglia. Another fact which goes to disprove Friedreich's supposition is that, as a rule, the cutaneous manifestations of this disease appear at once and at some distance from the origin of the nerve (resp. ganglion) in which pathological changes have taken place, whereas if the eruption were due to a progressive neuritis it would appear in successive crops.

(2.) The idea that the eruption of herpes zoster is due to vaso-motor paralysis as supposed by Eulenberg[2] and Landois[3] is also not competent. Disturbed innervation of the cutaneous blood-vessels can result only in anæmia or hyperæmia of the region of skin concerned or in the exit of some of the constituents of the blood into the surrounding tissues. Such cutaneous eruptions are those which consist of erythema in its various forms and in the production of wheals the type of this variety of cutaneous pathology being urticaria. Entirely different from the above are the changes which take place in herpes zoster, which consist in typical inflammatory processes, the responsibility for which it is impossible to place upon vaso-motor disturbance.

(3.) The majority of observers have contented themselves with supposing trophic disturbance without going more definitely into the question. The theory of Neisser and Weigert[4] that it is the death (necrosis) of superficial particles of the skin caused by disturbance of innervation which gives opportunity for the entrance of "infectious material" and consequent suppuration in herpes zoster is suggestive. In the opinion of the writer, leaving "infectious material" out of the ques-

[4] Eulenberg Real-encyclopädie, iv., p. 666.

tion, the death of portions of the skin is in itself sufficient to account for the eruption of herpes zoster. Each one of these necrosed portions acts as a foreign body upon the surrounding tissues, which react to such irritation with hyperæmia and inflammatory exudation. To show that disturbance of innervation is competent to cause death of tissue, the writer refers to the cases of acute decubitus which are seen in connection with disease and injuries of the spinal cord, and also to the cases of so-called herpes zoster gangrenosus in which the region of skin affected by the eruptions becomes necrosed, forming a sharply defined slough which extends into the corium. Kaposi's opinion that this gangrene is due to compression of the tissues by reason of hæmorrhage into the same is not supported by the fact that other cutaneous lesions in which hæmorrhages of much greater extent take place into the skin do not result as a rule in cutaneous gangrene. The writer considers that the simultaneous appearance of gangrene in all of the regions affected by the eruption of herpes zoster points to some cause situated in the nervous system. The hæmorrhages which take place in herpes zoster are easy of explanation. If necrosis affects the epidermis alone there results merely exudative inflammation without hæmorrhage, but if the corium becomes gangrenous, then the papillary and deeper blood-vessels of the skin are involved, and hæmorrhage to a greater or less extent takes place. The author sums up the matter as follows: "By reason of cessation of the function of certain nerves there is caused, in corresponding regions of the skin, the death of particles of tissue which may either be superficial and of microscopic size or of larger size and more deeply situated. The presence of such particles of necrotic tissue in the skin leads to reactive inflammatory processes which in the first instance result in the formation of vesicles without evident gangrene, and in the second cause the formation of a slough. It is probable that the above nerves arise in the spinal ganglia and in the Casserian ganglion, and that they accompany the sensitive nerves to the skin. The function of these nerves may be interfered with by disease of the ganglia, which is the most common cause of herpes zoster, or by inflammatory processes or injuries affecting them at some part of their course after leaving the ganglion from which they arise.

THE TUBERCLE BACILLU AND LUPUS.[1]

Koch[2] had placed at his disposal, for purposes of examination with regard to the presence of the tubercle bacillus, specimens from seven cases of undoubted lupus. The specimens from four cases consisted of bits of excised skin, and from the other three only the débris resulting from scraping was available. The bits of excised skin could alone be utilized for the purposes of direct microscopical examination. In each one of these four specimens the tubercle bacillus was detected, although only in a small number of preparations from each specimen, and only inside the giant cells. Such is the scarcity of the tubercle bacillus in lupus that in one instance twenty-seven and in another forty-three sections were examined before the bacillus was detected. It repeatedly happened, that after a number of sections were examined without showing the bacillus a group of successive sections, each containing from one to three bacilli, was met with. More than one bacillus was never seen in any giant cell. From each of the above seven cases inoculation of lupus material in the anterior chamber of the eyes of rabbits was made, and tuberculosis of the iris was produced in every instance, resulting in those animals which were allowed to live long enough (not immediately killed) in generalised tuberculosis. From one specimen of lupus the bacillus was cultivated, and inoculations of this cultivation upon animals were made with success in several instances.

THE SONG OF THE TUBERCLE BACILLUS.[3]

I.

Du hast ja die stärksten Gläser
Hast grossen Namen und Ehr'
Und hast auch die schärfsten Augen
O Koch — was willst Du noch mehr!

II.

Wir ruhten bisher in die Lunge
So sauft — da kamst Du daher
Und liessest uns Farbe bekennen
O Koch — was willst Du noch mehr?

III.

Du hast uns verpflanzt und gezüchtet
Auf Hunde — wie ordinär!
Und hast uns zu Grunde gerichtet,
O Koch — was willst Du noch mehr?

IV.

Wir büssten unser Prestige
Vom Auge stürzt uns die Zähr'
Wir kriegen noch selber die Schwindsucht
Vor Aerger — was willst Du noch mehr?

Hospital Practice and Clinical Memoranda.

MASSACHUSETTS GENERAL HOSPITAL.

FOUR CASES OF STRANGULATED HERNIA IN THE SERVICE OF DR. JOHN HOMANS.

REPORTED BY DR. CHARLES W. GALLOUPE, HOUSE SURGEON.

I. STRANGULATED HERNIA. HERNIOTOMY. RECOVERY.

ISAAC B., a Polish Jew, fifty years of age, entered on the night of July 26, 1883. Has had inguinal hernia on the right side for twenty-five years, which he has previously reduced by crossing his legs and pressing on the hernia with both hands. He has worn a truss only a portion of the time. He has had symptoms of strangulation several times, but never lasting over half an hour, and always disappearing with the reduction of the hernia. The present symptoms have lasted half a day.

At the time of entrance the scrotum was distended to the size of a man's head, hanging down nearly to the man's knees, and pyriform in shape. It was hard, tense, red, and sensitive to the touch. He had been vomiting *constantly* since the strangulation, and had had severe pain in the bowels for five hours.

He was etherized and a vertical incision was made over the ring by transfixing a fold of skin pinched up transversely. The tissues beneath were divided on a director, layer by layer, down to the peritonæum, and the intestine easily reduced without opening the peritoneal sac. A drainage tube, an inch and a half long,

was laid along the bottom of the wound and the skin sewed together with carbolized silk. A carbolized sponge covered with carbolized gauze and compresses of carbolized gauze were placed over the wound and held in position by a spica bandage, — the whole dressing being subsequently sewed firmly together.

July 28th. The dressing, being somewhat stained with blood, was changed under carbolic spray. The wound looked well, and the general condition of the patient was excellent. He took brandy, beef tea, and milk in small amounts at short intervals. Temperature at night 100° F.

July 29th. Last night the patient, who is extremely ignorant, tore off all the dressings and got out of bed to urinate. When discovered the intestine was down, forming a hernia the size of a cocoa-nut; this was easily reduced, however, the wound thoroughly carbolized, and a fresh dressing applied.

July 30th. Patient passes flatus freely, and to-day had two natural dejections.

August 3d. The drainage tube and the stitches were removed, and collodion and crêpe lisse "butterfly" put over the wound to prevent its gaping. No tenderness.

August 6th. Truss adjusted over an antiseptic pad, and patient allowed to walk about.

August 9th. Discharged well, wearing a truss which keeps the hernia in place.

Temperature normal throughout after the first twenty-four hours.

II. STRANGULATED HERNIA. OPERATION. DEATH.

John D., aged forty-five years, entered on the night of July 27th with strangulated inguinal hernia on the right side. He was ruptured many years ago, and has never worn a truss. For the past three days the hernia has been strangulated, and during that time he has been suffering severe pain and has been vomiting constantly.

At the time of entrance the scrotum was the size and shape of a man's head, red, tense, and sensitive. Patient was in a state of collapse, the pulse was very feeble, and the extremities cold.

The patient was etherized and a vertical incision was made over the ring; the tissues were divided on a director down to the peritonæum, which was then cut, giving exit to about a quart of thin, yellow fluid, which not only came from the hernial sac but ran out of the peritoneal cavity. The portion of intestine visible was of a dark-red color. The ring was divided, and the intestine finally put back with some difficulty. The wound was sewed up with silk (the stitches including the peritonæum), a small drainage tube was inserted into the peritoneal cavity, and a sponge and compresses of carbolized gauze tightly bandaged on. Patient vomited at intervals for three hours, complaining of intense thirst. Temperature 96° F. He was given brandy and milk by the mouth and rectum. The pulse improved a little, but he gradually became weaker, the skin being cold and moist, and he died at twelve o'clock P. M., about twenty-four hours after the time of entrance.

III. STRANGULATED HERNIA. OPERATION. RECOVERY.

John C., an Irish hostler, forty-seven years of age, entered the hospital September 5th, at eight o'clock A. M., with strangulated inguinal hernia of the right side. Nine months ago he came to the hospital with a strangulated hernia, which was reduced by the house officer without any difficulty. This time the hernia had been down for three hours, and during that time he had suffered constant pain and nausea. The hernia was the size of an orange, but very tense and hard.

Patient was etherized and an incision four inches long made over the ring, and the tissues carefully dissected off until the peritonæum was reached. An attempt was then made to reduce the hernia, but it was not successful. The peritonæum was then divided, allowing about half an ounce of fluid to escape. The intestine for a distance of three inches was congested and like liver in color, and was adherent to the neck of the sac. The ring was then divided, and the intestine easily replaced. A drainage tube was inserted into the abdominal cavity, the wound sewed with silk, and covered with a graduated compress of carbolized gauze and bandaged.

Patient had considerable pain, requiring opiates twice during the day. At midnight he vomited about two quarts of dark-colored extremely offensive material.

September 6th. Patient was ordered beef tea one ounce every two hours, alternating with brandy one ounce by rectum, with twenty-five drops of laudanum until pain and restlessness should be relieved, nothing being given by the mouth. The dressing was changed under carbolic spray and all antiseptic precautions, and the wound found to be looking perfectly well. Temperature 99° F. in the morning and 96° F. at night. Pulse 120 at night.

September 7th. Patient feels much better, although still very weak. The dressing was changed under spray and the wound found to be doing perfectly well. He has passed flatus several times. Temperature 99° F. to-night; pulse 80.

September 8th. Patient feels perfectly well. Enemata of beef tea omitted, and brandy one ounce given by enema every three hours. A teaspoonful of milk given by mouth every four hours. Had a good movement of the bowels this morning. To-night the temperature was 100° F., and the pulse 100.

September 9th. Has no nausea, but slight hiccough. Milk increased to two teaspoonfuls every two hours. Temperature normal; pulse 95.

September 10th. Bowels move normally; patient put on unrestricted liquid diet.

September 11th. All the sutures and the drainage tube left out. From this time forward the temperature fluctuated irregularly between 97° F. and 99° F., and the pulse between 70 and 90.

September 16th. Complained a little to-day of pain and burning in the stomach and vomited twice.

September 22d. Wound nearly healed. Patient up and about.

September 26th. There remains only a superficial granulating surface the size of a pea. Patient discharged, wearing a truss.

IV. IRREDUCIBLE HERNIA. OPERATION. RECOVERY.

J. S. B., a native of Scotland, forty-six years of age, walked into the hospital October 19th, and gave a history of right inguinal hernia for fourteen years; it has always been reduced for the greater part, but a small lump has remained outside the ring which he thinks is the testicle, as it is congenitally absent on that side. For the past four days the tumor has been the

size of a hen's egg, irreducible, and the skin over it is red and tender. He has no pain, vomiting, or other symptom.

October 20th. Patient was etherized and tumor cut down upon under carbolic spray and all antiseptic precautions. Before opening the peritonæum the greater part of the hernia was reduced with a distinct gurgle. The peritonæum was then divided, and there was no escape of fluid. A small lump of omentum, the size of a walnut, was found to be adherent outside the ring, which was then divided, allowing complete reduction. The testicle was nowhere to be seen.

The peritonæum was sewed up with a continuous catgut suture, entering at one end of the cut, traversing the wound, and emerging at the point of entrance; the two ends were then tied tightly, closing the wound by puckering it up. The skin was sewed with silk over a small drainage tube. A sponge and compresses of carbolized gauze were bandaged tightly on.

September 21st. Feels no discomfort. Temperature 100.5° F.

September 24th. Dressing changed under spray, and tube shortened to one half inch. Wound entirely healed except at point of exit of tube. Bowels moved by enema.

September 26th. Dressing changed; tube and stitches removed.

October 28th. Collodion and crêpe lisse "butterfly" applied to draw the wound together.

October 31st. Very small superficial wound remains. Graduated compress of carbolized gauze and spica bandage applied, the whole being firmly sewed together, and the patient discharged.

Reports of Societies.

BOSTON SOCIETY OF THE MEDICAL SCIENCES.

W. W. GANNETT, SECRETARY.

Meeting March 20, 1883.

Dr. Charles S. Minot gave an abstract of the results of recent investigations concerning

THE LIFE-HISTORY OF THE DISTOMA HEPATICUM,

the complete cycle not having been known until last year.

The eggs pass from sheep upon fields and from there are washed into pools. In the pools the larval form hatches, which swims about until it meets its first host, this being a snail, Lymnæus trunculatus. The larva gets into the animal, changes to a sporocyst, in which develop numbers of smaller larvæ, which are discharged from the cyst, pass through the body-wall of the host, encyst upon grass or elsewhere, and in turn are eaten by the sheep, in which they assume the adult form, thus completing the life-history.

Dr. J. Collins Warren made a preliminary report upon his investigations concerning certain changes observed in

THE HEALING OF ARTERIES AFTER LIGATURE.

Investigators who have interested themselves in the process of repair in arteries have considered the question usually from some special stand-point such as "the organization of the thrombus," "the part played by the white corpuscles," "the endothelium," etc. The object of this paper is to study the various pathological changes which occur in and around the vessel from the time the ligature has been applied until the process of cicatrization has fully completed itself.

These changes may be compared not inaptly to those which occur in long bones after fracture. In both we find an external and an internal callus, the former having only a provisional existence in the case of arteries, and subsequently giving place to a ligamentous union of the divided fragments, the latter undergoing such changes in the later stages of the process that the canal or lumen of the vessel is imperfectly reëstablished by the so-called "canalization" of the thrombus. In the mean time the walls of the vessel, like the cortical bone, have undergone certain changes which enable them to participate in the final process of repair.

When a large artery is tied in its continuity, the intima and a portion of the media are usually ruptured, and the adventitia is gathered into a dense tendinous-like sheath around the constricted ends. The first noticeable change is the formation of the thrombi and the development of a granulation-like mass of cells about the ligature, which if it has been cut short is completely enveloped by them. This appears to proceed from the connective tissue which surrounds the vessel, the periadventitial tissue. When the injury done by the constricting ligature is slight this new formation will be less in quantity, but if the coats of the vessel have been considerably bruised and a certain amount of extravasation has taken place, or the ligature has created irritation, the surrounding inflammatory tissue will form a well-marked callus. When one end of the ligature is left uncut or suppuration has taken place, the surrounding callus is imperfectly developed and secondary hæmorrhage is more likely to occur. Following the development of this tissue, we find it extends some distance up and down the sides of the divided vessel in the periadventitial tissue, the round cells of which it is composed invading only the superficial layers of the adventitia; at the point of ligature, where the fibres of the outer wall are densely packed, the cells at first do not penetrate at all; they follow the ligature as it cuts its way through, and indeed appear to exert a solvent action on the resisting fibres of the adventitia. As the walls thus liberated retract, the cells penetrate through various clefts and spaces, and eventually make their way into the clot and contribute more or less to the development of the internal growth. When a double ligature has been placed upon a vessel these cells find their way into the isolated central portions at the retracted ends and not through the walls directly as some investigators have supposed, and gradually disintegrate the various coats, invading them eventually from every point. The process, however, is a slow one, and requires several weeks for its accomplishment. If the artery has been properly removed from the body we find this growth forming a callus-like ring at the ligatured spot, in size about twice the thickness of the vessel. This was shown particularly well in the femoral artery of the dog killed on the tenth day. At the end of a month evidences are still present of such a cicatricial mass of tissue, but at three months a slender cord only unites the peripheral to the proximal end.

Early changes are seen in the proximal thrombus, well advanced already on the fourth day. In the carotid of a dog an abundant growth of young tissue was found budding from the ruptured ends of the media, and spreading in various directions throughout the clot, at-

taching itself to the wall at various points, and leaving spaces or meshes still occupied by the blood clot. As these fragments of clot become disintegrated and disappear, spaces are left into which blood eventually circulates, and the so-called "canalization" of the thrombus is effected. By the fifteenth day the new tissue has become very abundant, and has the appearance of granulations growing into and replacing the thrombus. By the end of a month we find but fragments of the thrombus remaining, and the granulations now present themselves to the lumen of the vessel. We find here a free communication between the spaces which separate these granulation-like masses and the lumen and an injection mass can be forced successfully for a considerable distance into them. The vessel walls are in the meanwhile undergoing certain changes. There is unquestionably a proliferation of the cells of the intima. This can be conveniently studied in those specimens where the distal thrombus is small, or in the space between two ligatures; the amount developed, however, is not sufficient to supply but a small fractional part of the internal callus. The rôle played by the endothelium appears to be one which furnishes a new endothelial covering to the cicatricial tissue and a lining to the new vessels that have been formed. Wherever the intima has been ruptured and the media exposed we find an intimate connection existing between it and the new tissue; at an early stage of the process cells are seen springing from the muscular layers and projecting into the thrombus; later one sees elongated spindle cells, like those forming the muscular layer, projecting from this layer into the newly-formed tissue, sometimes singly, sometimes in bundles, and occasionally occupying a considerable space.

At the point of ligature the elastic lamina appears frayed out, and is seen extending in various directions through the new tissue; the media begins by the end of the second week to retract, as also does the adventitia, leaving a space through which vessels eventually find their way, and communicate with those coming down from the lumen.

At the end of three months the cicatricial process is completed, the external callus has disappeared, and is replaced by a cord of connective tissue which joins the two ends of the vessel, now widely separated from one another. No traces of the thrombus are to be found, except a few pigment granules. A cicatrix, more or less voluminous, according to the size of the vessel and the situation of the ligature, is seen.

In the femoral artery of a large dog a very beautiful example of this was seen. The cul-de-sacs of the two ends were occupied by a semilunar mass of tissue, with its concavity towards the lumen. On the surface of this cicatrix was seen a thin layer of endothelium; beneath this was a crescent-shaped layer of cells, the horns extending up some distance on the sides of the vessels. These cells were parallel to one another and to the arc of the circle made by the layer. On a careful examination they were found to resemble more closely the *muscular* fibre cell than any other. The long prolongations and the staff-shaped nuclei were demonstrated by various methods of staining. A special series of stainings with aniline dyes and examination under Zeiss's oil immersion showed a close resemblance between these nuclei and those of adjacent muscular cells. Cross sections were confirmatory of this view. Below this layer was the body of the cicatrix, which consisted of interlacing fibres of connective tissue dotted over with masses of blood pigment. Through this tissue a large vessel made its way from the fundus of the cul-de-sac, rapidly diminishing in size and breaking up into branches, which anastomosed freely with a series of capillary vessels which lay between the slightly retracted walls of the vessel, and communicated with others in the slender ligament.

We see here an explanation of the immunity of cicatrices of this kind from aneurismal dilatation which occurs so frequently after wounds of vessels. The protective influence of the thrombus insures the development of a tissue closely resembling the three layers of the vessel wall, and having all the powers of resistance which they possess.

In the larger vessels of the human subject, where there is less muscular and more elastic tissue, the new muscular tissue is not so evident, but the connective tissue is greatly increased in quantity, and extends for a long distance into the lumen of the vessel. This was seen in a ligatured carotid artery of a man who died four years after the operation.

To summarize briefly, the ligatured artery is invested by a protective layer of new tissue formed from the periadventitial tissue, which, if well developed, gives great security against hæmorrhage until the permanent cicatrix has grown sufficiently strong. This may be likened to the provisional callus of bone. There is also an internal growth or callus formed from several sources, namely, the intima to a slight extent, the media more largely, also from cells finding their way from the periadventitia at a late stage through the retracted ends of the vessel. The thrombus is a mere passive structure, takes no part in the growth, but is protective, and affords an excellent medium for the new tissue to germinate in. When the provisional part of the internal callus has disappeared we find remaining a cicatrix closely resembling the three coats of the artery, and affording by virtue of its peculiar structures an equally effective resistance to the pressure of the blood column. The ligament which unites the two ends of the vessel represents in part the residue of the external callus, but also a portion of the walls of the vessel which have been absorbed during the inflammatory process. A vessel successfully ligatured in its continuity cannot, therefore, be said to have been "ulcerated" into two separate portions, but must be conceived of as a hollow tube which has solidified into a solid columnar mass of tissue a considerable portion of which subsequently shrinks into a cord.

NEW YORK ACADEMY OF MEDICINE.

AT a stated meeting of the Academy, held April 17th, DR. ROBERT ABBE read a paper on

DUPUYTREN'S FINGER-CONTRACTION.

This was the affection, he said, which Dupuytren described after making his dissection of the hand of a subject of deformity of the fingers who died in 1831, which demonstrated conclusively that the tendons, articulations, ligaments, synovial membranes, and bones remained entirely unaffected, and that the trouble was located in the palmar aponeurosis. A dozen dissections made since then had confirmed the correctness of the results of his investigations. Mr. Adams, of London, he continued, had given to the profession the best résumé of the subject which had yet appeared, and in

it he said that the anatomical conditions presented in Dupuytren's contraction all agreed in negativing the supposition that the tendons or sheaths of the tendons were involved. This was also confirmed by his own clinical experience, as he had invariably found that, after dividing subcutaneously a tense and prominent cord, which had generally been mistaken for a tendon, in the palm of the hand, the patient was immediately able to flex the finger as strongly as before the operation, at once disproving the opinion often expressed by surgeons that such fingers would remain stiff and inflexible after the operation. Of the course of the disease Mr. Adams says: The commencement of this form of contraction is sometimes to be traced in one hand in patients in whom the contraction exists in a severe form in the other, and I have watched its commencement from a flattened nodular induration in the palmar fascia in or just above the transverse crease in the palm of the hand corresponding to the metacarpophalangeal articulations. In the beginning the skin is not adherent to this flattened induration; but in the second stage the skin becomes adherent to the thickened fascia, and a puckered dimple is produced, extending from which towards the finger a thickened band of fascia can be distinctly felt. The third stage consists of an increased thickening of the palmar fascia and the band leading to the finger; and also the formation of a thick cord-like band of fascia, leading from the central thickening towards the annular ligament of the wrist, accompanied with a gradually increasing drawing down of the finger or fingers towards the palm of the hand.

This affection, Dr. Abbe went on to say, rarely occurred before middle life, and in a paper published by Dr. W. W. Keen, of Philadelphia, two years ago, in which he collected the statistics of all the cases that had then been reported, 105 in number, the average age of the patient at the time of the commencement of the trouble was found to be forty years. It was comparatively rare in women, occurring in only one case in twelve, and the ring and little fingers were the ones by far the most frequently affected. These statistics showed that the ring finger was implicated in eighty-eight cases, the little finger in seventy-seven, the index finger in thirteen, and the thumb in nine.

In the course of the paper Dr. Abbe gave a detailed description of the clinical history of the disease, dwelling particularly upon the associated pains and nervous disturbances which often characterized it, and suggested a "working hypothesis" for it somewhat as follows: —

The primary cause of trouble is a slight traumatism, which not infrequently escapes observation, and a spinal impression is produced by this peripheral irritation. A reflex impression is then conveyed to the part originally affected, resulting in the production of insensible hyperæmia and nutritive changes, which cause a permanent thickening of the palmar fascia and the formation of contraction bands binding down one or more of the fingers. Finally, through the tissue-contraction, there results a secondary series of neuralgic and other disturbances of sensation. The latter, he said, resembled to a considerable degree the manifestations of rheumatism; and in this connection he alluded to the nerve theory of acute rheumatism propounded a number of years ago by Dr. J. K. Mitchell, of Philadelphia, and the assertions of Weir Mitchell, Brown-Séquard, and others in regard to arthropathy. Mr. Adams's opinion was that Dupuytren's contraction nearly always depended upon a constitutional rather than any local cause, and essentially he regarded it as depending upon a gouty diathesis; but the hypothesis of a primary traumatism and reflex nervous irritation which he had suggested offered, he believed, a more satisfactory explanation of the peculiar phenomena of the disease. The not infrequent symmetry in the complaint had been regarded as a strong argument for its constitutional origin, but the production of sympathetic ophthalmia through the action of the ciliary nerves showed how a symmetrical affection could be produced by a purely local cause. In Keen's 105 cases the presence or absence of gouty trouble was noted in only forty-eight; but in no less than forty-two of these it was stated to be present. It could not be doubted, however, that in by far the larger proportion of the remaining cases there was no such complication, as it would have been mentioned in the histories given. When, therefore, the presence of the gouty diathesis was found he believed it to be simply a coincidence; but as gout was exceedingly prevalent among the upper classes of English society to which Mr. Adams's practice was, as a rule, confined, he could not wonder that that authority had been led to the conclusion which he had adopted. In this country, on the other hand, true gout was comparatively rare, and yet Dupuytren's contraction, as far as he was aware, was as frequently met with here as in England. In this disease he had little doubt also that traumatic trouble was responsible for results which were frequently attributed simply to rheumatism.

By way of illustration Dr. Abbe related, in more or less detail, the histories of ten cases of Dupuytren's contraction which had come under his observation, and upon the most of which he had operated. In connection with the histories he exhibited drawings and casts of the deformity existing prior to operation, and also presented two of the patients in person. The most remarkable of these cases was that of a German cloth-cutter, fifty-eight years old, in whom the ring and little fingers of the right hand, and the ring finger alone of the left hand, were affected. He had been a cutter for twenty years, and fifteen years previously the contraction of the left ring finger commenced. Soon afterwards the right ring finger also became affected, and some time after he began to suffer from a "lame back." The pain in the back at length became so constant and severe that he was obliged to give up work. This was three years before he was seen by Dr. Abbe. In the meanwhile he had consulted Dr. Seguin, who believed him to be suffering from organic spinal trouble, and in connection with Drs. Gibney and Amidon applied the actual cautery, the ice-pack, and electricity, both galvanic and static, without producing any appreciable result. At length, on account of the presence of the contractions of the fingers, Dr. Seguin referred the patient to Dr. Abbe, who had already published his first operation, with its successful results, and on the 24th of June, 1882, he performed Adams's operation, making six subcutaneous divisions in one hand and four in the other, dressing antiseptically, and applying straight splints. Even within ten days the man experienced the greatest possible relief from suffering. This patient had now been under observation for nearly two years, and the trouble in the back, as well as the hands, was entirely cured. He was then presented to the Academy, and it was seen that flexion

in the fingers was absolutely perfect, while extension was nearly, though not quite, complete. The other patient presented for examination was a gentleman sixty years of age, who, fifteen years before, had met with a slight cutaneous laceration of the palm of one hand. Within two months afterwards he noticed that a flattened bunch had formed, and subsequently the ring and little fingers of both hands became permanently contracted. About the first of February last Dr. Abbe made twenty subcutaneous cuts in each palm, applied antiseptic dressings, and made pretty full extension for two weeks. In consequence of the nerve irritation thus set up an attack resembling subacute rheumatism had been induced, but this had soon subsided, and very considerable improvement in the condition of the fingers had resulted. It was now eleven weeks since the operation, and on comparing the patient's hands with the plaster casts taken before the latter it was seen that while the fingers could be flexed to a much greater extent than before the cutting, the result was not as yet by any means complete. The trouble, Dr. Abbe explained, was not in the flexing at all, but in the hyperplastic condition generally of the fibrous tissues of the part, which could only be overcome after the lapse of a considerable period of time. The treatment by subcutaneous section and immediate extension, which Mr. Adams had devised, left nothing, he thought, to be desired. He had one suggestion to make, however, and that was, to avoid keeping up too forced extension, as this was liable to set up a considerable amount of irritation, thus illustrating the old aphorism, *ubi irritatio, ibi fluxus*. In concluding the paper he alluded to the treatment adopted by Professor Busch, of Bonn, as described by Madeling, but said he had had no personal experience with it. This operation belongs to the class of open wounds, and consists in dissecting up a triangular flap of skin from the contracted cord in the palm of the hand, and then dividing all the bands of the contracted fascia which can be reached; as the flap thus raised contracts the lower points of the wound may be united with sutures. A light bandage closes the wound; the hand is then kept by the patient in a sling, without the slightest attempt to preserve the extension. Extension-movements with the fingers are only made when the wound has entirely granulated, and then only in a gentle way. At first wood cylinders of various sizes are laid in the hand; later the hand is stretched on a back-splint. Active and passive movements are now to be made in and during the time the hand bath is used for cleansing the wound. The healing of the latter, accelerated perhaps by skin grafting, is accomplished in three or four weeks.

Dr. Alfred C. Post said he believed that he was the first American surgeon to direct attention to this subject, although of late years he had met with but few cases of Dupuytren's contraction. It was a matter of surprise to him that before the time of that surgeon the complaint should have been mistaken for contraction of the tendons, since in the former it made no difference with the fingers whether or not there was a flexed condition of the wrist or elbow, while this was not the case if the tendons themselves were contracted. He had been accustomed to operate by open section, and while he had had no difficulty in extending the fingers, he had found that a considerable interval of time must elapse before flexion could be well restored. All his cases had been of traumatic origin, and had, as a rule, occurred in those who, unaccustomed to manual labor, and with soft hands, had taken up gardening, rowing, or other kind of work in which the palm was exposed to blows or pressure, for purposes of recreation or exercise. The bruising of the palmar fascia, he believed, had always been the essential ætiological factor, and in no instance, so far as he remembered, had the patient been the subject of gout or rheumatism. The reason that the ring and little finger were so frequently affected, he thought, was because the thenar eminence, as it was called, was especially exposed to pressure in the handling of tools, walking with a cane, rowing, etc. In one of his cases he had found it necessary to divide the sheath of a tendon, but the tendon itself he had found entirely unaffected.

Dr. Frank H. Hamilton was of the opinion that in this disease there was a process of atrophy of the areolar tissue, resulting in a condition analogous to that known as *contracture* in tendons rather than an inflammatory one, and this, he believed, explained why such a long time must intervene before the power of flexion could be regained. There was some little doubt in his mind, he continued, whether the origin of the disease was traumatic in all cases. It had been observed that it was especially met with among coachmen in England, and it had occurred to him that the reason of this comparative frequency was that in their occupation this class of men kept their ring and little fingers (which, as had been shown, were almost invariably the seat of the contractions) almost constantly at rest, while they moved their other fingers freely. The persistent disease resulted, therefore, in this condition of atrophy of which he had spoken. On the whole, however, he thought the theory suggested by Dr. Abbe (which certainly did him great credit) was a sound one, and he also remarked that the possible neurotic origin of this affection was a subject which had occupied his own thoughts for a considerable time.

Dr. Sayre expressed similar sentiments, and went on to say that in all the cases that he had ever known of, pain, tingling, or other sensation of discomfort had preceded the deformity, the contraction, as a rule, not coming on until several months after this was first noticed. All the cases were traceable to a traumatism. Dr. Hamilton's suggestion in regard to the atrophy of the parts he thought an important one, and it was on account of this atrophic condition, he believed, that massage and similar manipulations were of so much service in this affection. They ought to be skillfully practiced for half an hour twice each day to restore the vitality and nutrition of the tissues, and in two cases he had by this means secured excellent results without resorting to any operative procedure whatever. The Adams operation in his hands had proved perfectly satisfactory, and it was the only one that he advised. Dr. Sayre also presented a plaster cast of one of his cases.

Remarks were also made by Drs. Weir, Gibney, Amidon, and A. L. Ranney, after which Dr. Abbe closed the discussion. He had no doubt that a great number of cases of Dupuytren's contraction were to be found all over the country, which were supposed to be cases of contracted tendons, and, therefore, irremediable, and said he believed that when the true nature of the affection and the benefit to be derived from the Adams operation came to be more generally understood, the most gratifying results might be anticipated.

After Dr. Post had published his cases, a number of years ago, the subject had in a great measure been allowed to drop out of notice until its recent revival by the English surgeons, and the appearance of Dr. Keen's paper, to which allusion had been made. The slow return of flexion of which Dr. Post and others had spoken this evening was a very noticeable feature of the cases, the fibrous tissues having gradually become so hardened and thickened that it required one or two years after the performance of the operation to restore them to their normal condition. He could not agree with Dr. Hamilton that the process was one of atrophy, but thought it was one of positive inflammation, the neurotic disturbances producing a continued hyperæmia, which finally resulted in hyperplastic thickening of the aponeurotic tissues and the formation of new bands of fascia. He thought that Dr. Sayre was inclined to attach too much importance to massage, which sometimes produced no benefit whatever, as in the case of the patient upon whom he operated eleven weeks ago, where it had been given a thorough trial. At the same time he considered it much better than stretching.

PHILADELPHIA CLINICAL SOCIETY.

STATED meeting, March 28, 1884. The President, DR. HENRY BEATES, JR., in the chair.

DR. DANIEL LONGAKER reported a case of

SUDDEN DEATH IN DIPHTHERIA.

The patient, Mary F., aged six years, was seen first on the afternoon of the second day of the disease. Her temperature was 104.25° F., and the general symptoms were of a decidedly adynamic type. She complained of pain and difficulty in deglutition, and a nasal tone of the voice was noticed. On inspection of the throat congestion and swelling were evident, and a small patch of false membrane was found on the right tonsil. The local trouble continued to grow worse until the fourth day, and was associated with a diminished secretion of urine, in which albumen was found to be present. The membrane was detached on the sixth day, and by the tenth convalescence was established. On the thirteenth day she was seen for the last time. Her pulse was a little accelerated in frequency and still weak. Her appetite was good, and she was sitting up and going down-stairs. Two days later, the fifteenth of the disease, after rising in the morning and feeling quite well, she suddenly fell from the chair from which she was attempting to rise, and expired.

DR. JOS. S. GIBB read a paper on

UMBILICAL HÆMORRHAGE.

In the preliminary remarks he spoke of the neglect of medical writers in omitting this important topic from their works, in spite of the oft-repeated mention of this negligence by individual observers, who, while investigating, have sought in vain in most of the standard works of the day for some account of this accident. Notable exceptions to this are the works of Simpson, Condie, and more particularly Dr. Bedford, of New York. The author spoke of the rarity of the accident, and proved the same by reference to the records of maternity hospitals and foundling asylums, and also by the experience of the older members of the profession, and finally presented a collection of 241 cases, which represented those which have been published since 1752.

The author's case was a female child of a "bleeder" mother. Hæmorrhage began on third day from birth; no single bleeding point was observed; the hæmorrhage was simply a continuous oozing from the bottom of umbilical depression. Several ligatures were applied directly to the cord, and then the ligature en masse, all of which failed to control the hæmorrhage. This was finally accomplished by a solution of the subsulphate of iron painted over umbilicus, and a pledget of cotton saturated with same solution bound fast over umbilicus.

The child suffered considerably from the profuse bleeding, though soon rallied after its cessation. Was strong and healthy when last seen, one month from date of accident.

There were no premonitory or accompanying symptoms. It was simply a spontaneous umbilical hæmorrhage.

The author makes three divisions of the subject: (1.) Hæmorrhage from improper ligation of cord. (2.) Hæmorrhage, the result of traumatism. (3.) Spontaneous hæmorrhage.

The first two received but cursory attention, the cause and remedy being apparent.

The third variety formed the true basis of the paper. He did not believe that any of the so-called premonitory symptoms, namely, colicky pains, jaundice, etc., can be relied on as such, but thought they may occur in otherwise healthy infants, or precede other affections. However, he laid stress on the fact of a hæmorrhagic diathesis existing in either parent, and believed this should make us watchful. He regarded the subjects of umbilical hæmorrhage as those suffering from a general disease, and hæmorrhage the first symptom of this disease. This symptom may occur at any time from a few hours to eight weeks after birth. The next most important symptom is jaundice. Both of these symptoms occur in an equal number of cases.

As regarded the ætiology, the author believed there is a direct relationship between the hæmorrhage and some constitutional condition of infant, which condition may be either hereditary or congenital. The hæmorrhagic diathesis was given a first place in the list of causes. It is not considered absolutely necessary to invoke the aid of the hæmorrhagic diathesis in the parent to establish the existence of this condition in the offspring; in other words, it may be congenital. Attention was drawn to the hæmorrhagic symptoms in these cases, namely, hæmorrhage from bowels, gums, and penis, as proof of this peculiar condition being a strong ætiological factor.

Jaundice was mentioned as forming the favorite ground of most writers on the subject as a causation of umbilical hæmorrhage, but the theories on which this is based were not regarded as substantiated by post-mortem examinations. In but few of the recorded cases were there any indication of a syphilitic or scrofulous taint. Various other minor causative influences were noted, namely, excessive use of alkalies by pregnant women, insufficient food, etc.

In conclusion it was admitted that in the present crude state of our knowledge of umbilical hæmorrhage we are obliged to admit several ætiological factors.

In an analysis of the reported cases there is found to be a strong predisposition on the part of the male to the occurrence of this accident. In 115 cases col-

lected where the sex is mentioned sixty-seven per cent. were males.

The morbid anatomy of the subject is very incomplete, being made up of statistics as to the patency or non-patency of the fœtal openings and vessels, the condition of the liver, and the character of the blood, from all of which no satisfactory conclusions can be drawn. The prognosis of umbilical hæmorrhage was stated as excessively grave. A mortality of eighty-three per cent. in 230 cases. The fatal termination may occur at any period from one hour to eight weeks from commencement of bleeding. In ninety-four cases where the time of death has been stated forty-seven, or fifty per cent., occurred within first forty-eight hours, twenty-five in the first, and twenty-two in the second, twenty-four hours.

The success of therapeutical measures the author believed lies in a proper appreciation of the nature and causes of the disease, and until this is accurately determined umbilical hæmorrhage will continue to resist all well-meant therapeutical resources.

In the present state of our knowledge the author believed that that treatment will be the most successful which consists of local styptics, ligature, etc., combined with such internal hæmostatics and tonics as experience has proven of value in kindred hæmorrhagic affections of adults.

Dr. Charles K. Mills. I have had one very interesting case of umbilical hæmorrhage, which recovered. The subject was the fourth child of perfectly healthy parents, the other three children being healthy. There was no trouble until the third day after birth, when an oozing was found at umbilicus, and the child vomited blood. The cord was examined, and found not bleeding at the extremity. Subsequently styptics were applied without result. The hæmatemesis occurred on three occasions during the following twenty-four hours of occasional hæmorrhage. The bleeding was finally controlled by transfixion with needles, and a half drop of aromatic sulphuric acid administered every two hours. The child recovered, and is now perfectly healthy.

Dr. Hannah T. Croasdale. I have had the opportunity of seeing but two cases of umbilical hæmorrhage. The first was from shrinkage of the cord and great amount of gelatinous material. After the ligature was closely reapplied the bleeding began again from the cut extremity. I then applied Pean's hæmostatic forceps and left them in position twenty hours. In the other case the hæmorrhage was controlled by tightening the ligatures.

Dr. Mary Willits. To the cases mentioned I would add one seen by myself in hospital. The child was a week or ten days old. After considerable hæmorrhage the bleeding was successfully checked by styptics and a compress.

Dr. Henry Beates, Jr. In connection with the hæmatemesis noticed by Dr. Mills, a case seen by myself showed at the autopsy gangrene of the ileum. There was also sloughing at the extremity of the cord.

Dr. Jos. S. Gibb. I am grateful to the members for the relation of their experience with this troublesome affection. The relation of the hæmorrhagic diathesis to it is yet a question. There seem, however, to be two things intimately connected with it, — the hæmorrhagic diathesis and jaundice. The case reported by Dr. Mills would rather support the former theory.

Dr. Albert H. Smith, in closing the discussion, said: I have seen two cases of the kind referred to by the reader of the paper. The first occurred at the end of twenty-four hours after birth in a healthy child. On attention being called to it the ligature was found loose; this was reapplied carefully. On the following morning the nurse again discovered hæmorrhage, and the child died before I could reach the house. This was not a case of neglect or traumatism. The other instance occurred also in a perfectly healthy child forty-eight hours old. The cord was ligated by myself, but I soon found hæmorrhage occurring freely from the tissue around the cord; a large compress of absorbent cotton was applied by means of Seabury & Johnston's plaster, and a teaspoonful of magnesia given internally. The child was saved. In these two cases there were no hereditary tendencies to this form of trouble; no jaundice; no purpura hæmorrhagica in either the mothers or the infants themselves. We have not, so far, reached any reasonable theory of its ætiology. Jaundice seems a coincidence. Great stress has been laid on hæmophylia, but my experience does not bear it out. In a family under my care four out of five died of hæmorrhage, but none showed any tendency to umbilical hæmorrhage. In the autopsies of fatal cases no uniform nor persistent conditions have been found. My cases are somewhat remarkable from the fact that recoveries are rare.

In the treatment we could hardly expect a compress to do much, yet I think this application the best that can be made. A laxative would contribute to lessen blood pressure and act as a revulsive.

I would suggest that hæmorrhage from non-application of a ligature would rarely occur in health if we are to judge by the fact that in Germany they seldom tie the cord. Difficulty may certainly arise from too early ligation. My practice is not to ligate until the cut extremity has ceased bleeding. It is evident that loosening the ligature would be a dangerous experiment in some of these cases.

Dr. Collins exhibited a bullet that had been removed from the anterior nares of a man. It had remained imbedded in the turbinated bones since 1865. An opening in nasal septum remains, produced at time of reception of wound.

Recent Literature.

Illustrations of the Influence of Mind upon the Body in Health and Disease, Designed to Elucidate the Action of the Imagination. By Daniel Hack Tuke, M. D., F. R. C. P., LL. D. Second American from the second English edition. Philadelphia: Henry C. Lea's Son & Co. 1884.

The mind acts upon the body through its threefold states of intellect, emotion, volition. The condition of the mind comprising these states exerts an enormous influence, for good or evil, upon the body with which it is associated — including in this term all sensations, movements, and organic functions.

Physiologically considered, the illustrations range over the effects produced by the action of the nerve corpuscles of the encephalic centres concerned in intellectual, emotional, and violitional states of mind, upon the sensory and motor ganglia, the centre of the sympathetic, and through the outgoing nerves, upon the whole body. The cases brought together in this

volume illustrate the importance of the truth that the mind or brain influences — excites, perverts, or depresses — the sensory, motor, vaso-motor, and trophic nerves, and through them causes changes in sensation, muscular contraction, nutrition, and secretion.

In these words, extracted from the "Introductory" portion, is comprehended the scope of Dr. Tuke's book. That the task he has assigned himself is not an easy one may be readily seen, but he faithfully fulfills his promises, as even a cursory glance at the succeeding chapters will show.

In the first chapter, which deals with General Psychological and Physiological Principles in reference to the intellect, Dr. Tuke shows that Muzer and Hunter a hundred years ago considered the subject of expectant attention, and later (1838) Johannes Müller. The latter, who agreed with John Hunter in regard to the influence of expectation, said: "It may be stated, as a general fact, that any state of the body, which is conceived to be approaching, and which is expected with certain confidence and certainty of its occurrence, will be very prone to ensue as the mere result of that idea."

Elliotson, Laycock, and others investigated the subject of magnetism, and Braid, so familiar to us all of the present day, systematized and repeated on a large scale the experiments which Hunter had previously performed on himself. Dr. Tuke speaks of the importance of Braid's conclusions, and frequently refers to them further on. Dr. Carpenter's exposition of the rationale of the phenomena of mesmerism, so far as they are due to the influence of expectant attention or dominant ideas, is also very valuable.

In section three of the second chapter (which is on the Influence of the Mind on Sensation) some interesting cases of what Dr. Tuke calls *psychical anæsthesia* are given. It is strange, he says (in a foot-note on page 61), "that in all, or nearly all, histories of anæsthetics, *psychical* anæsthetics are not even mentioned. Yet they preceded drug anæsthesia, and to a large extent suggested it. Cloquet removed a woman's breast during the mesmeric sleep, she being able to converse, but insensible to pain, so far back as 1829."

The most interesting cases of operation under the influence of magnetism were those of Dr. Esdaile, who in his book called Introduction of Mesmerism (with the sanction of the Government) into the Public Hospitals of India (second edition, 1856), records 261 rendered painless by this influence. Two hundred of the operations were for the removal of large tumors. There were also eighty-four capital operations in another hospital. Out of the 261 there were fourteen deaths, not dependent, however, on the operation.

On page 114 the Influence of the Intellect on the Blood-vessels is discussed with special reference to stigmata. The singular phenomena of stigmata, when genuine, arise from the mind's influence on the capillary circulation through the vaso-motor nerves. M. Alfred Maury has treated the subject of stigmatization in the most able manner. He mentions cases in which persons have dreamed that they received blows or wounds, and in the morning have found marks of inflammation on the body; "just so with visionaries," he says, "in them, under the power of the imagination, by the concentration of the attention, the blood is directed to the place where they fancy they are affected." M. Maury regards St. Francis d'Assisi as the ancestor of the stigmatized.

The stigmata of Louise Lateau are described, and the conclusions already arrived at in regard to their causation are said to be reaffirmed by M. Warlomont who carefully studied them. "The periodicity of the stigmata is rationally accounted for by the ideas with which they originated having been associated with certain days; and by the weekly direction of thought and feeling in the same channel. The profane are not now allowed to study the case of Louise."

These few extracts from the book of Dr. Tuke give an idea, in a limited manner, of the interesting matters discussed. They fail, however, to give even a faint idea of the strength of treatment, the rich coloring and clearness and skill of style, with which every subject is elaborated.

Dr. Tuke has been known for many years as an able writer, and has of late especially interested himself in trance conditions. The book before us is valuable for what it contains on this subject, which has lately assumed such importance.

As physicians we should constantly bear in mind the importance of the expectant treatment of disease. We probably all suppose that we know almost everything about this treatment now, but Dr. Tuke's book, which we should all own and read, will make the modest among us hang our heads.

The bibliography and general index at the end of the book are excellent.

A Manual of Obstetrics. By A. F. A. KING, M. D. Second Edition; 12mo, 338 pages. Philadelphia: H. C. Lea's Son & Co. 1884.

This manual was designed by the author "to present, in an easily intelligible form, such an outline of the rudiments and essentials of obstetric science as may constitute a good ground-work for the student at the beginning of his obstetric studies." The book is confessedly a compilation, in great part, from the more extensive and classical treatises, such as those of Lusk, Playfair and Leishman. The author has succeeded in producing an epitome, which, if at times concise at the expense of graceful expression, is a reliable and sufficiently comprehensive outline of the subject. Our fear is, however, that manuals like this one will to a great extent displace the large treatises from the student's library: if the knowledge of a manual will enable a student to pass for his degree, he will only exceptionally buy and study the larger works, and will therefore enter his profession with crude and chiefly empirical knowledge, ill-prepared to deal rationally with the problems of medical practice. C. M. G.

Ninth Report of the State Board of Health of Minnesota. Minneapolis: 1883.

The Reports of Local Boards and officers relative to the prevalence of small-pox in 1881 and 1882 occupy a large portion of the report, and show that the disease was generally prevalent throughout the State in those years.

Brief reports follow upon Meteorology, Sanitary Water Survey, Typhoid Fever, Diphtheria, Trichinosis, and Vaccination.

An account of the proceedings of a two days' Sanitary Conference at Minneapolis, in which it is notable that seven out of twenty papers presented on sanitary subjects were written by clergymen.

Medical and Surgical Journal.

THURSDAY, MAY 1, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

THE MEETINGS OF THE AMERICAN MEDICAL AND OTHER ASSOCIATIONS AT WASHINGTON.

WASHINGTON is to be this week and next the great centre of medical interest, and no other place in the country to-day offers nearly the same advantages and inducements for the annual gatherings of the National Associations. It is easy of access by various lines of railways from all directions; it is central for a very large proportion of the population of the Union; it contains almost unrivaled collections both of books and specimens of general, scientific, and strictly professional interest; it has grown to be a very beautiful city, with environs many of which are charming and replete with historical associations; and in it all American citizens are at home. Moreover, it offers, with the vicinity of Baltimore, in common with places otherwise less favored and more distracting though less diverting, sufficient comfortable accommodation for all who choose to resort to it. If more inducements were needed the easy and rapid escape from a climate still harsh and uncertain, and the pleasing anticipation of a tardy spring, should be a temptation hard to resist for the medical fraternity of New England. There is the choice between going all the way from Boston by water in a little over forty-eight hours, or directly through by rail in about seventeen hours; the dweller in the interior is likely to wisely choose the former, but we can sympathize with a resident on the coast who might think he had had of late enough east wind.

The last days of this week will be occupied by the American Surgical Association, which offers a very large number of papers on a great variety of subjects, and by the new Climatological Association, for which a vast amount of material is waiting over our many degrees of latitude and longitude. Massachusetts Bay alone offers climate enough for a vigorous Association's attention. Next week will be fully occupied by the American Medical Association's meeting, and those of the Medical Editors, of the Council of the Public Health Association, and of the representatives of the State Boards of Health.

We do not doubt these bodies would all find it for their advantage to meet more frequently in Washington than they now do, every fourth year being at present the rule with the American Medical Association.

There is one regrettable feature this year, which threatens to mar the otherwise fair prospects of the meeting of the Medical Association; we refer to the exclusion, not merely from the business meetings but from participation in the Sections as well, of those opposed to the Association's Ethical Code. It is understood that such men are neither to be allowed to read papers, nor to take part in the discussions of other's papers; whether or not this exclusion is to be extended to those also who merely decline to take an oath to support a code is not clear. In either case it is to be feared that what might have been a serene and scientific atmosphere will be disturbed if not poisoned and stifling.

THE DOCTRINE OF EVOLUTION AS APPLIED TO PATHOLOGICAL STATES OF THE NERVOUS SYSTEM.

IN Dr. Hughlings Jackson the Spencerian philosophy has found a strong supporter. The recent Croonian lectures on the Evolution and Dissolution of the Nervous System are a rigid application of Mr. Spencer's principles to the explanation of nervous pathology.

The nervous system in its development is a striking illustration of the general law of evolution, which it is sought to apply to all orders of natural phenomena. This is seen whether we study the nervous system as an ascending development in the animal kingdom, or in the light of human embryology. It is an advance from the simple to the complex, from the relatively undifferentiated to the relatively differentiated, or as Hughlings Jackson expresses it in the lectures above alluded to, from the most to the least organized — that is to say, from the lowest well organized centres up to the highest least organized centres, the latter being the most complex, the most heterogeneous, and the most unstable. The triple conclusion, then, to which Jackson arrives is, "that the highest centres which are the climax of nervous evolution and which make up the organ of mind are the least organized, the most complex, and the most voluntary."

One of the most interesting chapters in Dr. Maudsley's recent work, Body and Will, treats of the future probable disintegration and decline of will power in the human race by a reversal of the solar conditions which have evolved it. Without, however, speculating as to any such possible contingencies, we are continually meeting instances of disintegrations in the delicate nervous plexuses which form the substratum of mind by causes which produce local failures of nutrition. Dissolution is treated of by Dr. Jackson as a process of *undevelopment*, a "taking to pieces" in the order from the least organized, the most complex, and the most voluntary toward the most organized, the most simple, and most automatic. Such "dissolution" (which of course is only partial) is equivalent to the statement, "reduced to a lower level of evolution." Dr. Jackson applies this thought to the elucidation of the phenomena of insanity: "Starting with health, the assertion is that each person's normal thought and conduct are or signify survivals of the fit-

test states of what we may call the topmost layer of his highest centres, the normal highest level of evolution. Now suppose that from disease the normal highest level of evolution — the topmost layer — is rendered functionless. This is the dissolution, to which answer the negative symptoms of the patient's insanity. His positive mental symptoms are still the survival of his fittest states, — are survivals on the lower but then highest level of evolution. The most extravagant actions and the most absurd mentation in insane people are the survival of their fittest states. We need not then wonder that an insane person believes in what we call his illusions, they are his perceptions. His illusions are not caused by disease, but are the outcome of activity of what is left of him; his illusions are his mind."

The above view of abnormal mental action — as being a result of suspension or inhibition of the supreme centres and the unchecked activity of the lower — is now a favorite view with mental pathologists.

Dr. Jackson gives interesting illustrations of his meaning, of which one of the simplest is the effect of alcohol on the brain (and here we take occasion to remark that a similar conception was presented by John Fiske in a work published fifteen years ago): "An injurious agency, say alcohol, taken into the system flows to all parts of it, but the highest centres being least organized 'give out' first and most, the middle centres being more organized resist longer, and the lowest centres being most organized resist longest. Did not the lowest centres for respiration and circulation resist more than the highest do, death by alcohol would be a very common occurrence."

After stating that in the progress of chronic alcoholism gradual involvement of the lower centres takes place, he speaks of local dissolution. Disease may occur in any evolutionary level on one side or on both sides; it may affect the sensory elements chiefly, or the motor elements chiefly. There are local dissolutions of the lowest centres and of the highest centres. In every case of insanity the highest centres are affected, and different divisions of these highest centres are affected, corresponding to different kinds and degrees of insanity.

As examples of local dissolution, Dr. Jackson cites first progressive muscular atrophy. This is dissolution commencing at the bottom of the central nervous system. Here atrophy begins in the most voluntary limb, the arm, affecting first the most voluntary part of the limb, the hand, and spreading to the trunk (the more automatic parts). The wasting of the muscles of the hand has its causal counterpart in atrophy of the first or second dorsal anterior horn, an atrophy which, as its name intimates, is progressive.

He next refers to hemiplegia resulting from destruction of a plexus in mid region of the brain. The arm, the most voluntary limb, suffers the more and longer, and the most voluntary part of the face suffers more than the rest of the face. Although unilateral movements (the voluntary) are lost, the bilateral, which are more automatic, are retained. "Hemiplegia is a clear case of dissolution, — loss of the most voluntary movements of one side of the body, with persistence of the more automatic movements."

His next illustration is paralysis agitans. Here the tremor begins in the hand, affecting the whole arm, finally becoming bilateral. "In an advanced stage paralysis agitans is double hemiplegia with rigidity; is a two-sided dissolution." The same conception is applied to hemilateral epileptiform seizures and to chorea, the great elaborateness of whose movements "points to disease high up, to disease on a high level of evolution."

Dr. Jackson's next example is aphasia, which in many ways illustrates the doctrine of dissolution. In complete aphasia, for instance, there is loss of intellectual (the more voluntary) language, with persistence of emotional (the more automatic) language. In other cases the patient has lost all speech with the exception of "yes" and "no," "the most automatic of all verbal utterances."

Speaking of uniform dissolution, dissolution affecting all divisions of the highest centres, Dr. Jackson chooses as an example delirium in acute non-cerebral disease. This, scientifically considered, he says, is a case of insanity. "The patient's condition is partly negative and partly positive. Negatively he ceases to know that he is in the hospital, and ceases to recognize persons about him. In other words, he is lost to his surroundings; he is defectively conscious. We must not say that he does not know where he is because he is defectively conscious; his not knowing where he is is itself defect of consciousness. The negative mental state signifies, on the physical side, exhaustion or loss of function, somehow caused, of some highest nervous arrangements of the highest centres. We may conveniently say it shows loss of function of the topmost layer of his highest centres. The other half of his condition is positive. Besides his not knowings there are his wrong knowings. He imagines himself to be at home or at work, and acts as far as practicable as if he were; ceasing to recognize his nurse as a nurse he takes her to be his wife. This, the positive part of his condition, shows activity of the second layer of his highest centres, but which, now that the normal topmost layer is out of function, is the then highest layer. His delirium is the 'survival of the fittest' states on his then highest evolutionary level. Plainly he is reduced to a more automatic condition. Being (negatively) lost from loss of function of the highest, latest developed, and least organized, to his present 'real' surroundings, he (positively) talks and acts as if adjusted to some former 'ideal' surroundings, necessarily the more organized."

These lectures will be read with interest by all who desire to investigate the great questions of neuro-psychology.

— The use of mullein as a palliative for the cough of phthisis seems to be meeting with favor in various quarters. The customary form of administration has been a milk decoction of the plant. More recently the smoking of the leaves has been recommended as a more agreeable and effective method of administration.

THE SUBCUTANEOUS USE OF MORPHINE IN ELDERLY PERSONS.

The fact is generally recognized and taught that the very young and the very old are peculiarly susceptible to the toxic effects of anodynes, especially opium. In the case of children, particularly, we have learned the necessity of reducing materially the dose of opium beyond the proportion to the adult dose which the age of the child would indicate for other drugs. We think, however, that many practitioners do not attach sufficient importance to the necessity for caution in the administration of opium to the aged; and in particular that the hypodermic method, useful as it is under certain circumstances, is capable of greatly increasing the risk of an overdose in such cases. One eighth of a grain of morphia given under the skin has caused alarming symptoms in an elderly subject, and we have seen a similar dose apparently cause death in a hospital patient suffering from pneumonia. Instances have occurred within the knowledge of many where a dose as small as one sixth of a grain repeated once in the course of an hour has proved fatal to a feeble and aged subject. What enhances this danger is the fact that symptoms indicative of narcosis are often entirely wanting until the repetition of the dose has been made, when they supervene with alarming suddenness. It is just here that the risk of the hypodermic method is seen. If the drug is in the stomach and symptoms of an alarming nature present themselves there is at least an opportunity to evacuate the residue of the drug before it becomes absorbed. But with the narcotic circulating within the blood-vessels it is beyond our reach. The very elements which have made the hypodermic syringe such a favorite in the hands of the medical profession are those which constitute its chief danger.

True it is that Magendie's solution is convenient to carry about; but so would be morphia granules if we were as accustomed to them. The taste of the latter is no great obstacle to their use; the nausea and other bad after-effects are hardly more frequent after the administration of the drug per os. The desideratum of concealing the dose from the patient is as readily attained by the use of the pill as by that of Magendie's solution. Many physicians finding difficulty in preserving the solution without some antiferment are in the habit of dissolving a weighed powder each time; and surely this is no more convenient than to carry and administer a small pill.

The indications which are especially met by the hypodermic method are quickness of action and the retention of the drug against vomiting. When either of these requirements must be met the subcutaneous injection should be practiced. But for a routine method, and above all in that class of patients who are especially liable to suffer from an overdose of the drug, it seems to us unjustifiable to employ a channel of administration which takes it out of our power to evacuate what may prove an excess of the medicament. Some over-conservative physicians of our acquaintance have gone so far as to throw aside the hypodermic syringe altogether in view of the risks which they have observed in its use. But while this extreme ground seems to us untenable, and while we recognize the great advantages which in certain special cases may accrue from hypodermic medication, we yet feel impelled to protest against making the subcutaneous tissue a regular channel for the administration of morphia, especially in the debilitated and aged.

DR. WILLARD PARKER.

The name of Dr. Willard Parker, who died at his residence in New York on the 25th of April, has long been a household word, and not only in the city where the last forty-five years of his life were spent, but also throughout the country. For eighteen months past he has been suffering from pyelitis and other troubles, but the immediate cause of death was an attack of apoplexy, with aphasia, which occurred April 13th. He was born on the 2d of September, 1800, at Hillsborough, New Hampshire, but when he was five years old his father, who was a farmer of Puritan stock, removed to the family homestead at Chelmsford, Massachusetts; which remained in Dr. Parker's possession up to within a short time before his death. When he was eighteen he began teaching school in order to get the funds necessary to secure a collegiate education, which his parents were unable to provide for him, and four years afterward he entered Harvard; from which he was graduated in 1826. It is related that when he entered college he expected to study for the ministry, but that an incident which occurred in his Freshman year led to a change in his choice of a profession. His room-mate had an attack of strangulated hernia, and he was so much impressed with the skill with which the late Dr. John C. Warren reduced it, thereby affording complete and instantaneous relief, after a local practitioner had failed in the attempt, that he decided to study medicine himself. After graduation he became a student under Dr. Warren, and in 1830 received the degree of M. D. from Harvard; in the meanwhile having served for some time as an interne at the Chelsea United States Marine Hospital. He immediately received the appointment of Professor of Anatomy in the Vermont Medical College, and in the same year (1830) accepted a similar appointment in the Berkshire Medical College, Pittsfield, to which the professorship of surgery was added in 1833. He became Professor of Surgery in the Cincinnati Medical College in 1836, and while still holding this position made a trip abroad, and studied for some time in the London and Paris hospitals. For a period of thirty years, beginning in 1839, he was Professor of Surgery in the College of Physicians and Surgeons in New York; at the expiration of which he resigned this position, and accepted the chair of Clinical Surgery. His success in that city was immediate, both as a teacher and a practical surgeon, and his brilliant operations and distinguished talent as a lecturer soon placed him in the foremost rank of the profession and carried his fame even across the Atlantic.

His exalted character also won the esteem and

veneration of the entire community, and, a public-spirited citizen of the noblest type, he always took an active part in all projects to promote the general welfare. Thus he was scarcely less prominent than the late Dr. James R. Wood in the reorganization of the city almshouse and hospital system in 1845, which resulted in the foundation of Bellevue Hospital, and he was also instrumental, to a large extent, in securing the reorganization of the Health Department, which was previously altogether inefficient. He was closely identified with the temperance movement, and in 1865 he was appointed to succeed Dr. Valentine Mott as president of the State Inebriate Asylum at Binghampton, the first establishment ever founded for the treatment of drunkenness as a disease. In 1870 the degree of LL. D. was conferred upon him by Princeton College. Among his contributions to surgical science were the operation of cystotomy in chronic cystitis, an operation for the repair of rupture of the perinæum and sphincter ani, which involved the division of the coccygeal attachments of the sphincter, and an operation for the cure of abscess of the appendix vermiformis, while he was also the first to direct attention to concussion of the nerves as distinguished from concussion of the nerve centres.

The funeral services were held April 28th at the University Place Presbyterian Church, and, in accordance with Dr. Parker's expressed wish, were of a very simple nature. The church was filled with his medical and other friends, all the various societies to which he belonged being represented, and the pall-bearers were eight grandchildren of the deceased. On the day following the remains were taken for interment to New Canaan, Conn., where for a number of years Dr. Parker had owned a country residence and farm, and spent a considerable portion of his time.

MEDICAL NOTES.

— Etherization by the rectum has been tried with success at the Boston City Hospital in several cases.

— The Senate of Massachusetts has passed a bill requiring life insurance companies within the State to remove the discrimination in tariff which they have heretofore maintained against negroes. It seems improbable that legislation of this sort can effect any good object. The former rules of the insurance companies were in no sense an oppression of the colored race. If the rates were higher to them it was because experience had shown that their expectation of life was not so good as that of whites, and all that remains now for the companies is to decline to accept risks on negroes at all, which is no great gain to the latter. Such laws, if not mere political buncombe, are examples of legislation undertaking to fix the price of commodities, and are not likely to prove particularly successful.

— A case of delirium tremens is reported in the British journals occurring in a boy in Dublin at the age of eight. He stole a quantity of whiskey and drank it, thereby acquiring an attack of delirium tremens, which nearly killed him. He had been a dipsomaniac from the time he was able to imbibe alcohol in any form.

NEW YORK.

— The governors of the New York Hospital Society, which has under its charge the Chambers Street branch, and the Bloomingdale Insane Asylum, as well as the main hospital on Fifteenth Street, have presented their one hundred and thirteenth annual report to the Legislature. From the insane department thirty-six patients, fifteen men and twenty-one women, were discharged during the year cured, and thirty-eight improved, ten of whom bade fair to recover under sufficiently protracted treatment. During the summer and autumn months excursion parties of patients, varying in number from ten to forty, of both sexes, were taken semi-weekly, either to one of the more retired sea-side resorts or to the asylum farm at White Plains, and with the exception of the drowning of a young man while in bathing, which was an unavoidable accident, no untoward event occurred; while the amount of pleasure and healthful benefit derived by the participants was undoubtedly very considerable. Twelve patients, four men and eight women, accompanied by their attendants, were boarded in private families in the country for periods varying from a few weeks to three months, and this also proved beneficial to them. It is stated that ten of the twelve, although well satisfied with their accommodations while away, were glad to return to the institution. Dr. Nichols, the medical superintendent, advises that as there is a great want of available skill in the personal care of the insane during the periods when they are from necessity or choice treated at their homes, a course of from three to six months in institutions for the insane should be added to the curriculum of the training schools for nurses. In furtherance of this idea he offers to give the graduating nurses of the New York Hospital school this extra course, which he thinks would be of benefit to the asylum as well as the nurses. No mechanical restraint was used during the whole year; although it was found necessary to keep one patient, a man of powerful frame suffering from acute mania, secluded most of the time, as the best means to husband his strength and secure the safety of others.

— At a meeting of the Board of Estimate and Apportionment held April 21st $138,710, from the excise fund, was distributed among various charitable institutions in the city. Of this sum the St. John's Guild and Floating Hospital received $2300; the New York Diet Kitchen Association, $1175; the House of Rest for Consumptives, $1094; St. Luke's Hospital, $4312; St. Francis' Hospital, $7656; Mount Sinai Hospital, $4250; the German Hospital, $4541; St. Vincent's Hospital, $1975; the Presbyterian Hospital, $2687; St. Mary's Free Hospital for Children, $1531; the Woman's Hospital, $1852; St. Joseph's Hospital, $1500; the New York Eye and Ear Infirmary, $2208; the New York Ophthalmic Hospital, $1439; the New York Orthopædic Dispensary, $2220; and six of the other dispensaries $1000 each. The Purim ball,

which was given a few weeks since at the new Metropolitan Opera House in aid of the Hebrew Orphan Asylum, netted the very handsome sum of $14,150.

— In the early part of April one of those pretentious and "thoroughly fire-proof" apartment-houses, of unnumbered stories in height, which have recently sprung up like mushrooms all over New York, was almost completely burned up, and although the fire occurred at midday several of the occupants barely escaped with their lives. If it had taken place in the night the loss of life would undoubtedly have been considerable, and as it was the new life-saving scaling ladders (in the use of which a corps of the Fire Department has been specially drilled, and the efficiency of which were on this occasion practically tested for the first time) had to be employed for the rescue of the elevator boy, who was at the top of the house, and whose escape was cut off by the dense smoke. Since then a bill has been passed by the State Senate, entitled An Act to Regulate the Height of Dwelling-Houses in the City of New York, and for the better Preservation of Health in said Houses, which provides that the height of dwellings shall be proportionate to the width of the streets in which they are built, as is the case in Paris, and as Dr. Van der Poel suggested as a requirement by law in a recent report of the Committee on Hygiene of the County Medical Society. A resolution has also been introduced into the New York Board of Aldermen providing that on streets and avenues not exceeding sixty feet in width the houses shall not exceed sixty feet in height, and in streets and avenues exceeding sixty feet in width they shall not be more than seventy feet in height.

Correspondence.

A NEW ANTISEPTIC DRESSING.

Worcester, Mass., *April* 23, 1884.

Mr. Editor, — Since the first week of February last I have been treating compound fractures and operation wounds at our City Hospital with what I suppose to be a new form of dressing. It is certainly simple, its essential elements being but two in number, the "absorbent sheet lint," supplied by Dennison & Co., and a glycerine jelly containing bichloride of mercury. An ounce of gelatine is softened in cold water enough to cover it, then a pound of glycerine is added, and the mixture kept hot until it becomes homogeneous; meanwhile twelve grains of the sublimate is added, and promptly dissolves. This jelly is quite fluid at 110° F., but is firm at ordinary temperatures. Once prepared it can be kept indefinitely in a glass jar.

I closely cover the wound with one or more layers of the absorbent lint dampened with one five-thousandth solution of the sublimate, and over this brush or pour the warm fluid jelly. This instantly fills the meshes of the lint, and makes an air-tight and germ-tight seal to the wound. Outside of this I bind a thick layer of dry sublimated absorbent lint or cotton.

I have found it convenient to prepare, in advance, broad strips of the lint by passing them through the hot jelly; the lint comes out quite heavily charged, and for convenience of handling is laid at once upon a broader strip of dry sublimated lint to which it adheres as it cools. This keeps very well in a tight jar, and for any fairly even surface this makes an excellent dressing, not requiring to be warmed.

The cases reported show that under either form of this dressing a wound may remain aseptic, and heal as well as under the Lister dressing. Under it I have not yet found it necessary to use drainage tubes, as there has been no exudation or suppuration.

I think this will be found a convenient and useful dressing in hospital and private practice. It is simple, light, clean, odorless, comfortable, and, so far as my experience has gone, it is thoroughly antiseptic.

George E. Francis, M. D.

Miscellany.

A CASE OF PUSTULA MALIGNA.

Dr. A. C. Griffin, in the *New York Medical Journal* (April 12th), describes a case of septic poisoning which, in his opinion, was malignant pustule, caused by the bite of a green-bottle fly which had been feeding on a heap of offal. The fly bit the patient on his cheek sufficiently to draw blood, and was killed by a friend. The following day the patient presented himself with a swelling on the cheek at a point corresponding with the bite, the appearances of which are thus described: —

On examination the swelling was found to be of a somewhat circular form, about twenty-five mm. in diameter, and extending through the whole thickness of the cheek, implicating the skin and mucous membrane, to which it was firmly adherent. The swelling was indurated to such an extent as to greatly resemble the ivory hardness of carcinoma. It was extremely sensitive to pressure, and the patient complained of very severe lancinating pains radiating through it. In the centre of this swelling, fifteen mm. above and twenty mm. external to the ala of the nose, was situated a small ulcer, which was covered by a closely adherent layer of pus of a grayish, unhealthy appearance. Surrounding the ulcer was a wide areola of an angry red, erysipelatous hue. The cervical and submaxillary lymphatics were enlarged and tender to pressure. Pulse 120, temperature 103.2° F., tongue slightly coated, violent headache, and complete anorexia. The patient complained of great prostration, excessive nervousness, and an extreme fear of impending death. The ulcer was cauterized with pure carbolic acid, cooling lotions applied, and quinine and alcohol freely administered, with sufficient morphia to relieve pain. On the following day the condition of the patient was much worse, the induration had greatly enlarged in size, extending from the upper lip to the orbital cavity, also implicating the nose, being fully sixty mm. in diameter. The ulcer had also increased by a process of sloughing to a diameter of twenty mm.; the destruction of tissue was quite extensive, as the ulcer extended nearly through the thickness of the cheek. The edges of the ulcer were composed of exuberant granulations, quite protuberant, and bled quite freely from the slightest contact, and from the cavity thus formed there was a profuse discharge of a thin, ichorous fluid of a peculiarly offensive odor. Delirium now supervened. Pulse 140, temperature 104.8° F., tongue heavily coated with a brownish-yellow fur, the bowels were constipated, the cervical lymphatics were very much en-

larged, quite tender to pressure, and threatening suppuration; the patient meanwhile complained constantly of severe pain. Pure carbolic acid was again applied to the ulcer to destroy the exuberant granulations, and to prevent, if possible, further septic absorption. Poultices were applied over the swelling, morphine, quinine, and alcohol were given in increased doses; a mild cathartic was also administered. The patient grew progressively worse until the sixth day from the receipt of the bite, when his condition was one of extreme prostration, with very little hopes of recovery. The treatment had consisted of thorough cauterization of the ulcer each day, poultices to the swelling, and the free use of alcohol and quinine, with sufficient morphine to allay the pain. By the aid of this free stimulation the patient was enabled to overcome the virulence of the septic inoculation, and on the seventh day his condition had slightly improved. The induration became somewhat softer and slightly diminished in size, the ulcer began to assume a healthy appearance, normal granulations sprang up covered with laudable pus, and the areola had become less vivid in color. From this time on the case progressed favorably, the induration of the cheek and the swelling of the glands subsided, the cavity left by the ulcer filled up and healed, leaving a moderate-sized cicatrix, and the patient's general condition advanced steadily toward its normal standard.

Though the clinical evidence in this case seems to point to malignant pustule, no examination was made for the presence of the bacillus, nor was any experiment made by inoculation. In view of the comparative infrequency of this disease in this country it is to be regretted that this confirmatory evidence was not obtainable.

A similar case, also resulting from the bite of a fly upon the cheek, was reported in the *Gazette des Hôpitaux*, No. 102, having occurred in the service of M. Mollière at the Hôtel Dieu at Lyons. Energetic treatment by thermo-cautery and the injection of the swollen parts with twenty per cent. solution of carbolic acid caused a slough which was complete in a week and was followed by rapid healing. Here the blood and serum in the vicinity of the pustule showed a few filaments of the bacillus anthracis, and an inoculation practiced therewith produced death in a few hours with signs of specific gangrenous infection.

THE MORAL BEARINGS OF ARTIFICIAL IMPREGNATION.

THE French journals have been commenting freely during the past few weeks on a decision rendered by the Tribunal of Bordeaux in regard to a case of artificial impregnation. A physician had employed this device with the consent of a childless couple, but unsuccessfully. Not being paid, he brought suit for the amount of his fee, and detailed in court the steps of the treatment. This evidence the court held to be in contravention of the requirements of professional secrecy, and at the same time went a step further and pronounced against the performance of artificial fecundation as being repugnant to natural law, and capable in cases of abuse of causing a real social danger. On the former point, the violation of professional confidence, the general opinion seemed to support the decision (which was confirmed on appeal by the Tribunal of the Seine), but on the latter point the Society of Legal Medicine appointed a committee to prepare a report. This report was presented by Dr. Leblonde, and while condemning the attempts of irregular practitioners to attract sterile women by means of advertisements of an operation for their relief, it indorses the operation when performed by an honorable physician who resorts to it only under well-determined conditions, and with discretion, as a perfectly acceptable device, which, instead of creating a social danger, may conduce to the extension of the family without in the least offending modesty.

Reviewing the conditions essential to impregnation, the report says that when the two necessary elements are both existent and of normal quality a mechanical obstacle may interfere with their contact, due to malformations of the male or female organs of generation, such as hypospadias, uterine deviations, atresia cervicis, etc., and that in such cases artificial impregnation is equally legitimate with other surgical measures for the overcoming of the obstacle. For this operation he quotes as authority Courty, Pajot, De Sinéty, Lutaud, Eustache, Marion Sims, Gaillard Thomas. The method of Pajot, in the opinion of the reporter, is preferable on the ground of simplicity and decency. Of the success of the manœuvre nothing is said in the report, but the implication is made that the accomplishment of the desired result is an easier matter than we are inclined to think has been the experience of American gynæcologists.

The conclusion of the report was as follows: "So far from condemning artificial fecundation, as does the Tribunal of Bordeaux, we are disposed to encourage it as tending to perpetuate the species and furnishing to the family joys which it could not otherwise experience. However, we are of the opinion that the operation ought not to be attempted except at the express request of the persons interested, and after assurance of the quality of the seminal fluid furnished by the husband."

To this the Society added by unanimous vote this amendment: "An honorable physician ought not to take the initiative in proposing the operation of artificial impregnation, but neither ought he to refuse to practice it at the request of the interested persons."

THE CRYPTA SYPHILITICA.

WE wonder how Professor Hayem will feel when in *Gaillard's Monthly*, in an article by Ephraim Cutter (reprinted in the *Therapeutic Gazette*, and in pamphlet form by a prominent pharmacist), he sees his *hæmatoblasts* depicted as "embryonal forms of vegetative spores" of the "crypta syphilitica!" It is added that "in the diagram they are immovable, but in the blood just removed from the stream of a syphilitic, and viewed under a one-sixteenth-inch first-class Tolles' immersion objective they appear as auto-mobile globes, active with life, skurrying hither and thither with the ceaseless, playing motions of protoplasmic life." Marvelous are the powers of Stillingia! Professor Hayem will be pleased to learn that these little highly refractive bodies, so well described in his treatise on the blood, can be entirely removed by a course of McDade's syrup!

— "Doctor," said the grateful patient, seizing the physician's hand, "I shall never forget that to you I owe my life." "You exaggerate," said the doctor mildly, "you only owe me for fifteen visits; that is the point which I hope you will not fail to remember."

REPORTED MORTALITY FOR THE WEEK ENDING APRIL 19, 1884.

Deaths reported 2424 (no reports from St. Louis, New Orleans, Buffalo, Milwaukee, and Providence): under five years of age, 848; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 368, lung diseases 371, consumption 352, diphtheria and croup 101, scarlet fever 64, diarrhœal diseases 41, typhoid fever 36, measles 24, whooping-cough 23, erysipelas 16, malarial fevers 11, cerebro-spinal meningitis 10, puerperal fever eight, typhus fever one. From *typhoid fever*, Philadelphia 12, Chicago and Boston four each, New York, Baltimore, and Cincinnati three each, Brooklyn two, Pittsburg, Nashville, Lowell, Springfield, and New Bedford one each. From *measles*, Philadelphia five, Baltimore eight, New York and Chicago four each, Brooklyn three. From *whooping-cough*, New York seven, District of Columbia three, Brooklyn, Chicago, Boston, Baltimore, and Cincinnati two each, Pittsburg, Worcester, and Brookline one each. From *erysipelas*, New York seven, Brooklyn four, Boston two, Philadelphia, Baltimore, and Newton one each. From *puerperal fever*, Brooklyn and District of Columbia two each, Philadelphia, Chicago, Boston, and Nashville one each. From *malarial fevers*, New York five, Brooklyn four, Baltimore two. From *cerebro-spinal meningitis*, Chicago two, New York, Baltimore, Cincinnati, District of Columbia, Nashville, Fall River, Cambridge, and Fitchburg one each. From *small-pox*, Philadelphia, Chicago, and Cincinnati one each. From *typhus fever*, New York one.

One case of small-pox was reported in Cincinnati; scarlet fever 58, diphtheria 19, typhoid fever two, and measles one.

In — cities and towns of Massachusetts, with an estimated population of — (estimated population of the State 1,955,104), the total death-rate for the week was — against — and — for the previous two weeks.

In the 28 great towns of England and Wales, with an estimated population of 8,762,354, for the week ending April 5th, the death-rate was 22.7. Deaths reported 3809: acute diseases of the respiratory organs (London) 357, whooping-cough 184, measles 143, scarlet fever 75, fever 41, diarrhœa 37, diphtheria 28, small-pox (London 13, Birmingham three, Liverpool and Sunderland two each, Newcastle one) 21. The death-rates ranged from 14.3 in Brighton to 36.2 in Oldham; Leicester 16.5; Birkenhead 17.8; Bradford 18.9; London 21.9; Sheffield 22.4; Birmingham 23.3; Liverpool 23.6; Newcastle-on-Tyne 24.5; Nottingham 26.9; Leeds 28.1; Manchester 30.4. In Edinburgh 23.7; Glasgow 26.2; Dublin 29.6.

For the week ending April 5th, in the Swiss towns, there were 36 deaths from lung diseases, consumption 33, typhoid fever 25, diphtheria and croup 18, diarrhœal diseases 13, whooping-cough eight, scarlet fever two, erysipelas two, measles one. The death-rates were, at Geneva 20.4; Zurich 19.7; Basle 21.7; Berne 33.3.

The meteorological record for the week ending April 19th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps: —

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM APRIL 19, 1884, TO APRIL 25, 1884.

HOFF, JOHN VAN R., captain and assistant surgeon. To be relieved from duty at Alcatraz Island, Cal, and to report to the commanding officer at Fort Mason, Cal., for duty as post surgeon. Paragraph 3, S. O. 45, headquarters Department of California, April 16, 1884.

PORTER, JOSEPH Y., captain and assistant surgeon. Granted leave of absence for two months, to take effect about May 5, 1884. Per S. O. 38, headquarters Division of the Missouri, April 19, 1884.

BIART, VICTOR, captain and assistant surgeon. Granted leave of absence for one year on surgeon's certificate of disability, with permission to leave the Division of the Missouri. Paragraph 2, S. O. 91, A. G. O., April 19, 1884.

LA GARDE, LOUIS A., captain and assistant surgeon. Granted leave of absence for one month, with permission to apply for two months' extension. Paragraph 1, S. O. 91, A. G. O., April 19, 1884.

OFFICIAL LIST OF CHANGES IN THE STATIONS OF MEDICAL OFFICERS UNITED STATES NAVY FOR THE WEEK ENDING APRIL 26, 1884.

HIBBETT, C. T., passed assistant surgeon, ordered to United States Iron Clads, James River, Va.

AULICK, H., passed assistant surgeon, detached from Iron Clads and ordered to the New Hampshire.

DIXON, W. S., passed assistant surgeon, detached from the Hartford and ordered to the Coast Survey Steamer Hassler.

TERRILL, F. H., passed assistant surgeon, detached from the Hassler and ordered to the Hartford.

WISE, J. C., surgeon, detached from the New Hampshire and placed on waiting orders.

SCHOFIELD, W. K., medical inspector, appointed medical inspector on active list.

NASH, F. S., passed assistant surgeon, detached from Laboratory and ordered to the Alert (Greely Relief Expedition).

HALL, J. H., passed assistant surgeon, ordered before Retiring Board.

NELSON, H. C., medical inspector, placed on retired list.

BATTLE, S. W., passed assistant surgeon, placed on retired list.

TERRILL, F. H., passed assistant surgeon, resigned.

MURRAY, J. M., passed assistant surgeon, ordered to the Minnesota.

AMERICAN CLIMATOLOGICAL ASSOCIATION. — The first annual congress of the American Climatological Association will meet at the hall, northwest corner of Sixth and F Streets, Washington, D. C., May 3 and 5, 1884. Sessions ten A. M. and three P. M. Papers: (1.) Opening Address, F. I. Knight, M. D., Boston, Mass. (2.) The Ætiology of Pulmonary Phthisis, B. F. Westbrook, M. D., Brooklyn, N. Y. (3.) Dryness and Elevation the most Important Elements in Climatic Treatment of Phthisis, Charles Denison, M. D., Denver, Col. (4.) Some Observations on the Diagnosis of Pulmonary Diseases, D. N. Kinsman, M. D., Columbus, Ohio. (5.) The Effects of Humidity on the Cause and Course of Diseases, W. H. Geddings, M. D., Aiken, S. C. (6.) The Effects of Sea-Air on Diseases of the Respiratory Organs, Boardman Reed, M. D., Atlantic City, N. J. (7.) The Use of Compressed and Rarefied Air, as a Substitute for Change of Climate, in the Treatment of Pulmonary Diseases, J. Solis Cohen, M. D., Philadelphia, Penn. (8.) The Constituents of Climate and their Relation to Disease, J. Hilgard Tyndale, M. D., New York. (9.) The Relation of Laryngeal to Pulmonary Diseases, F. H. Bosworth, M. D., New York. (10.) The Climate of Large Cities Dangerous to Consumptives, Frank Donaldson, M. D., Baltimore, Md. The above is a list of the papers already reported to the Committee. Others have been promised, but the titles have not been sent in.

AMERICAN SURGICAL ASSOCIATION. — The exercises of the annual meeting of the American Surgical Association will be held in the lecture hall of the National Museum (Smithsonian Grounds), Washington, D. C., Wednesday, Thursday, Friday, Saturday, April 30, May 1, 2, and 3, 1884, from eleven A. M. to four P. M. The profession is cordially invited to attend the sessions.

SUFFOLK DISTRICT MEDICAL SOCIETY. SURGICAL SECTION. — The last regular meeting of the Season will be held at 19 Boylston Place on Wednesday evening, May 7th, at 7.45 o'clock. Communications: —

Cases of Strangulated Hernia, Inguinal and Umbilical. Dr. A. T. Cabot.

Cases of Unilateral Atrophy, and

A Case of Strangulated Umbilical Hernia. Dr. H. L. Burrell.

S. J. MIXTER, *Secretary*, 180 Marlborough Street.

APPOINTMENT. — William H. Welch, of New York, has been appointed Professor of Pathology in Johns Hopkins University.

DEATH. — In Roxbury, Mass., April 24, 1884, William Henry Campbell, M. D., M. M. S. S., aged fifty-two years.

BOOKS AND PAMPHLETS RECEIVED. — Post-Nasal Catarrh and Diseases of the Nose causing Deafness. By Edward Woakes, M. D. Illustrated with Wood Engravings. Philadelphia: P. Blakiston & Co. 1884.

A Course of Instruction in Zoötomy (Vertebrata). By T. Jeffery Parker, B. Sc. Lond., Professor of Biology in the University of Otago, New Zealand. With seventy-four Illustrations. London: Macmillan & Co. 1884.

National Board of Health. Remarks before the Committee on Public Health of the House of Representatives . . . in Refutation of Charges made against the Board by Supervising Surgeon-General of the Marine Hospital Service. Washington, D. C.

Original Articles.

MALIGNANT PUSTULE.[1]

BY W. S. JANNEY, M. D.

My remarks to-night will be on the clinical history of four cases of malignant pustule, which have come under my observation at various times during thirty years of practice.

The synonyms of malignant pustule, as given by various authors, are: Contagious carbuncle, malignant carbuncle, anthrax, and charbon; other names are used to designate the more diffused and general forms of the disease.

It is defined to be a specific contagious disease, communicated to man from disease of horned cattle, horses, sheep, and other herbivora, and known as splenic fever, and due to the presence in the system of the bacillus anthracis of Cohen, or bacteridium of Davaine. The local or external form of the affection, malignant pustule proper, is a carbunculous swelling having specific characters, attended with more or less intense surrounding inflammatory œdema; constitutional symptoms may be slight or severe, and the disease is often fatal.

The symptoms and course of malignant pustule vary greatly with the form of disease. Authors describe at least three distinct forms: —

First, malignant pustule or carbuncle proper, the form from which the names of charbon and anthrax are derived; usually it occurs as a primary lesion due to direct inoculation; the seat is either on the face, neck, hands, or arms, those parts most exposed to inoculation.

Second, malignant anthrax, œdema, without definite pustule, corresponds in the main with malignant pustule proper. The eyelids are the parts most frequently affected, but it may occur elsewere.

Third, internal anthrax; differs greatly from external, and may be general, having no special lesion or accompanied by local affection; usually pulmonary or gastro-intestinal.

The cases that I wish to report to-night come under the form of malignant pustule proper.

Mr. H., residing in Hopewell township, Mercer County, N. J., a farmer, aged sixty; previous to the attack general health good. On the morning of September 20, 1866, Mr. H. noticed a small pimple on his right cheek, immediately over the infra-orbital foramen. During the day it was slightly painful, and during the night the apex became vesicular, with great itching and burning, which continued to increase until the following morning, when I first saw him. The face presented the following appearance: a small pustule, one eighth inch in diameter, situated as above stated, with a denuded apex of a dark-brown color, and an areola of one half an inch in diameter, of a dark red color, surrounding the base of the pustule, and not sensitive to touch; pulse 78, respiration 20, tongue slightly coated, and bowels constipated. During the day the temperature increased. Pulse in the evening 100, respiration 22. Side of face up to this time had become very much swollen, with red streaks extending to the neck; slightly delirious; tongue dry. Free crucial incisions were made in the pustule. Delirious through the night of the 21st. On the morning of the 23d respiration was 30, pulse 130, tongue brown and dry; the cheek was of dark gangrenous color, extending to the lower margin of lower jaw, and also backward, involving the parotid region and right ear, to near the posterior median line of the neck; dark-red streaks extending over the shoulder to the right arm; patient becoming rapidly comatose, and died at two P. M. on the 23d, being fifty-eight hours after first noticing pimple on his face. The inflammation and œdema did not extend over the median line of the face or back of the neck.

The second case that came under my care was: —

Mrs. R., residing at her country seat in the suburbs of this city, thirty-two years of age, married, the mother of three healthy children, and of previous good health. She noticed September 17, 1876, a small pimple on the right side of the face, one half inch below the lower lip, and slightly to the right of the median line. From her description of how it commenced, she informed me that her first intimation of anything being the matter was a persistent itching sensation, and on rubbing it she felt a small circumscribed induration, which was in the skin, and was not noticeable. She continued rubbing it to allay the itching; in a few hours she noticed a slight elevation of the skin, conical in form, and the size of an ordinary pin-head, which increased during the day. Slept well during the night, and on the following morning, the 18th, she noticed the papule had increased in size, and was vesicular, containing a dark-colored fluid. The itching continued, and on rubbing it she ruptured the vesicle, and from that time she had a burning, itching pain in the pustule. I saw Mrs. R. on the morning of the 18th of September; she was sitting in her room and did not consider herself sick; had slight headache; was nervous, and spoke of a premonition of impending sickness or calamity. She had an anxious expression; retraction of the eyelids, giving her a staring expression. Tongue slightly coated with a light yellow coat; temperature 99°, respiration normal, pulse 80; constipated, and urine scanty; on her face, half an inch below the right side of the lower lip, and half an inch to the right of the median line, was a pustule of the size of a split pea, with an indurated base half an inch in diameter, of a dark-red color. The apex of the pustule was denuded of cuticle, and of a dark-brown color, not sensitive to pressure; no lines or streaks of inflammation extending from the pustule; no œdema of face. On the evening of the 18th temperature was 100, pulse 110, respiration 22; tongue coated and dry; streaks or lines of a dark red color, extending from the right side of pustule in a line of the inferior maxilla, curving upwards towards the right ear; right half of lower lip swollen, and of a dark-red color, which, on pressure, imparted a nodulated condition; dark-red streaks extending from the lip, curving upwards to the integument over the malar process. The skin and underlying tissues between the base of the pustule and the indurated lip retained their normal color and consistence.

Complained of severe lancinating pain over right half of face and shoulder. Morning of the 19th, temperature 101½, pulse 124, respiration 24; tongue dry; sordes on teeth; the areola around the pustule not so red; no discharge from pustule; dry and dark in color. The lower right half of lip showing dark gangrenous patches; right half of upper lip swollen, of a dark purple color, hard and nodulated. The right half of the face,

[1] Read before the Philadelphia County Medical Society, April 9, 1884.

forehead, and right ear swollen, œdematous, and of a mahogany color. The right side of neck swollen, with red streaks extending to the shoulder and arm. Complains of lancinating pains in right arm, fore-arm, and hand; also of scalp.

I saw her again on the evening of the 19th, when all of the above symptoms were aggravated. The right half of the face and right half of forehead, scalp, neck, and arm presented the appearance of rapid extension of gangrene. The lower half of right lip completely gangrenous; upper lip also. The fauces, tonsils, and pharynx not affected; lancinating pains in right mammary region, abdomen, and lower extremities. There was no redness, œdema, or other indications of the disease extending to the mammary region, abdomen, or right lower extremity. Skin normal in color; the slightest touch of the integument over the right side of the thorax, thigh, and leg produced the most excruciating pain, and not upon the left; became comatose during the night of the 19th. On the morning of the 20th, gangrene had extended during the night to the shoulder and arm, as far as the elbow, and to the median line of the neck posteriorly; had stertorous breathing; temperature 108, respiration 30; died at twelve o'clock, seventy-two hours after she had first noticed the papule.

The third case:—

Mrs. H., residing in this city; was called to see her October 20, 1878; thirty years of age, and of previous good health; mother of five children. Found her dying. She had been under the treatment of another physician. The history of the case was obtained from her husband. Four days previous to her death she noticed a small papule on the right side of her chin; on the following night the lower lip began to swell, extending to the median line, and next day involving the right half of the upper lip and extending over the left side of the face; complained of lancinating pain over right side of face, head, and neck; was five months pregnant, aborted on the third day, became comatose on the night of the third day, and died on the morning of the fourth day. When I saw the case, the lower and upper right half of the lips were gangrenous; between the pustule and lower lip an area of healthy tissue intervened, similar to case second.

The fourth case occurred in this city:—

Mr. P., residing at 2140 Park Avenue, a wool merchant, aged twenty-four, and of previous good health, who had been in Colorado, purchasing wool, returned from Colorado, October, consulted me October 3, 1883, for a cough, the result of a cold. On examination I observed on the face, one inch below the right half of the lower lip, near the median line, a small papule, not larger than a small pea, with an areola half an inch in diameter, of a pale pink color. I directed his attention to it, and he remarked that it was nothing but an ordinary pimple. My experience with the cases reported led me to suspect that it might be the beginning of a malignant pustule. As he had been handling wool in Colorado I stated my suspicions, and asked him to call next morning, incised the papule, and applied a fly-blister. He attended to his usual business on the 3d of October, and called at my office on the morning of the 4th. The papule had not increased in size. The areola was of a much darker color, but not increased in area. I removed the vesicated skin from the papule, and applied another blister. Had headache, temperature 99, and respiration 20. I felt almost convinced that I had to encounter another case of this dreadful disease. By much persuasion he permitted me to incise the pustule freely; was requested to go home, and told that I would see him in the evening.

On the evening of the 4th temperature 100°, pulse 95, respiration 20; no perceptible change in the pustule; red lines extending outward from left side of pustule, curving upwards over the face; lower right half of lip swollen and hard, with a band of hardened tissue extending from the left angle of the mouth outward for two inches; the face œdematous.

Incised the lower lip transversely from the median line to the angle on the line of junction of the skin and mucous membrane to the depth of one inch, and applied pure carbolic acid to the wound; also injected pure carbolic acid into the pustule; applied a poultice of flaxseed, tar, and tinct. iodine — three parts of meal, one part of tar, two dr. of tinct. iodine.

Morning of the 5th, inflammation around pustule less; lower lip more swollen, and presenting a gangrenous slough; left half of upper lip swollen and presenting the same appearance as lower lip twelve hours previous. Temperature 101, pulse 115, respiration 22; face more œdematous, and dark-red lines extending from the lips upwards and backwards to the zygoma and left orbit. I incised upper lip, and applied carbolic acid and poultice; injected carbolic acid into the tissues near the angle of the mouth; applied lint wet with sol. act. lead to the face. Evening of the 5th, temperature 102½, pulse 124, respiration 24; the œdema of the face has not extended beyond the limits in the morning; tissues of upper lip of darker color; lower lip sloughing; pustule and surrounding areola improving in color; slight discharge of pus from pustule.

Morning of the 6th. Passed a very restless night. Temperature 102, pulse 120, respiration 20. Tissues of lower and upper lip sloughing; removed with forceps and scissors a great portion of the slough of the lower lip; continued to apply carbolic acid. The œdema and color of the face remained in much the same condition of previous day. Evening of the 6th, temperature 103, pulse 130, respiration 24. No perceptible change in the pustule, lips, or face since morning.

Morning of the 7th, temperature 102⅔, pulse 128, respiration 22; œdema of face diminished; pustule and lips discharging pus. Evening of the 7th, temperature 103⅜, pulse 135, respiration 26; has been chilly during the day, and is in a profuse sweat at six P. M.

Morning of the 8th, temperature 102⅔, pulse 126, respiration 22; sloughing of upper lip profuse. Evening, temperature 104, pulse 140, respiration 30.

Morning of the 9th, temperature 103, pulse 138, respiration 28; entire slough of lower lip removed, presenting a healthy granulating surface. Upper lip sloughing; removed from angle of mouth a large slough; face less swollen and less discoloration. Slightly delirious during the previous night. Evening, temperature 105, pulse 142, respiration 30.

Morning of the 10th, temperature 102, pulse 130, respiration 28. Night, temperature 103, pulse 130, respiration 34. Condition of face improved; slough removed from upper lip.

Morning of the 11th. Passed a restless night; had slight chill followed by a profuse perspiration; temperature 103⅕, pulse 140, respiration 28; tongue dry, and sordes on teeth; bowels loose; redness and œdema of face rapidly disappearing; the lips presenting healthy

granulating surfaces; swelling and fluctuations below the symphysis of lower jaw; punctured, and half ounce of pus evacuated. Evening, temperature 105½, pulse 130, respiration 30.

Morning of the 12th, temperature 102, pulse 130, respiration 28; profuse perspiration through the previous night. Evening, temperature 103⅜, pulse 140, respiration 28.

Morning of the 13th, temperature 100, pulse 106, respiration 24. Swelling with fluctuation over infra-orbital foramen. Punctured, and evacuated one ounce of pus. Evening, temperature 103, pulse 140, respiration 30.

Morning of the 14th, temperature 99, pulse 110, respiration 22. Profuse perspiration, alternating with chilliness during the previous night and day, and complains of pain and soreness of right leg. On examination found an area of dark-red color, one inch wide and two inches long, situated on the outside of the anterior border of the tibia, at the junction of the middle with the upper third of the bone. Introduced bistoury to the depth of one inch and a half, without reaching pus.

Morning of the 15th, temperature 100⅜, pulse 132, respiration 24; passed an uncomfortable night; had profuse perspiration; wounds of lips improving. Evening, temperature 104, pulse 140, respiration 32.

Morning of the 16th, temperature 103, pulse 140, respiration 30. Severe chill during the night, followed by severe lancinating pain in lower right pleura. The swelling in the leg continued, and a deeper incision, extending between the tibia and fibula, gave exit to three ounces of dark-colored pus. Evening, temperature 105, pulse 160, respiration 36.

Morning of the 17th, temperature 102 3/10, pulse 128, respiration 30; had alternate chilliness and perspiration during the night. The acute pain in the side relieved, with a dull aching pain ensuing; slight cough on full inspiration. Percussion revealed dullness over the lower lobe of right lung. Evening, temperature 104⅜, pulse 140, respiration 36.

Morning of the 18th, temperature 104¼, pulse 128, respiration 30; expectorates frothy mucus, tinged with blood; continues to have profuse perspiration several times a day, so that his clothing is continually wet.

Morning of the 19th, temperature 101, pulse 126, respiration 28. Expectoration of bloody sputa increased. Perspiration continuing. Abscess in leg discharging unhealthy dark-colored pus. Evening, temperature 103, pulse 132, respiration 32.

Morning of the 20th, temperature 101, pulse 124, respiration 28. Expectoration of a dark-brown color. Less dullness on percussion. Abscess still discharging pus of a lighter color. Evening, temperature 103⅜, pulse 132, respiration 30.

Morning of the 21st, temperature 100, pulse 120, respiration 22. Expectoration less and of lighter color. Urine examined; quantity thirty ounces daily, and slightly albuminous. Evening, temperature 102⅜, pulse 128, respiration 26.

Morning of the 22d, temperature 101, pulse 124, respiration 26. Expectoration less. Less dullness over lung. Evening, temperature 103, pulse 130, respiration 30. . . .

Morning of the 25th, temperature 99, pulse 120, respiration 22. More air entering right lung. Less cough and expectoration. Otherwise no improvement. Evening, temperature 102⅜, pulse 128, respiration 30. . . .

Morning of the 28th, temperature 99⅜, pulse 124, respiration 24. Less cough and expectoration, and profuse perspiration at intervals of four to six hours. Evening, temperature 103, pulse 132, respiration 30.

Morning of the 29th, temperature 99⅛, pulse 120, respiration 22. With the exception of temperature, the patient appears to be improving. Evening, temperature 103, pulse 130, respiration 24. . . .

On the night of November 1st he had a severe chill, after which the temperature rose to 106°, followed by severe pain in left thorax, which proved to be the beginning of another attack of pleuro-pneumonia, which passed through all the stages that I have just related in the attack on the right side, with temperature, pulse, and respiration during the course of the disease a counterpart of the first attack.

On the morning of the 10th of November, temperature 102½, pulse 130, respiration 28. Patient continued to improve from this date. A slight cough with expectoration of light-colored sputa continued until December 28th, with occasional attacks of perspiration; the temperature was taken until the 28th of December.

The characteristic symptoms of two of these cases were alike in several respects. The locations of the pustules were both on the right side of the face, and located at the same place. The intermediate integument between the pustules and lips was not affected by the disease in either case. The inflammation or extension of the disease appeared to be from the right side of the pustules along the integument covering the basilar portion of the inferior maxilla, to near the angle of the jaw, and then curving upwards over the face along the anterior border of the masseter muscle.

On the second night, or twenty-four hours after pustules were noticed, and twelve hours after red streaks or lines extended along the lower margin of jaw, and then the lower half of the lips became affected, and twelve hours after the upper lip became affected in both cases, and then the right half of the face, forehead, and scalp in the case of Mrs. R., and the face of Mr. P. became œdematous.

From the observation of these cases it appears that the disease may be divided into four periods or stages: first, the period of incubation, which may be from a few hours to fourteen days, with no prodromes; second period, the formation of pimple, papule, and pustule, lasting from twelve to twenty-four hours; third stage, the extension of the œdema and inflammation, occurring twelve hours after the formation of the pustule; fourth, the stage of gangrene, occurring in from twelve to twenty-four hours later. The disease extended by the poison being carried by the superficial lymphatics only. I am led to this conclusion from the fact that in three of the cases the disease extended from the right side of the pustule, curving upwards over the face; and not until the lines of inflammation or œdema had reached above the line of Wharton's duct did the lips show evidence of disease. Again, the disease in all of the cases was confined to one side of the face, head, neck, and scalp, and did not pass over the median line of the face or the median line of neck posteriorly. The treatment of all of the cases was similar in most respects.

In the second case, Mrs. R., the treatment was free crucial incision of the pustule; injection of pure carbolic acid into the pustule; quinia in large doses, car-

bonate ammonia, tinct. ferri chloridi, and whiskey punch internally; free incision of the lips, and injection of pure carbolic acid, with local application of alcohol to the face.

The third case, Mrs. H., I did not treat.

The fourth case, Mr. P., was under my care from the time the papule was formed; free crucial incision was practiced at once, and pure carbolic acid was injected into the tissues around the pustule; he was put upon quinia, four grains every three hours; tinct. ferri chloridi, thirty drops every three hours, and whiskey punch. As soon as the lips showed indications of the disease free incisions were made, and carbolic acid was injected into them, and also into the angle of the mouth; lead-water and laudanum applied to the face, which appeared to act better than alcohol; used as a poultice, linseed meal, tar, and tinct. iodine; when indications of septic poisoning occurred he was given aqua chlorinata in drachm doses every four hours, which was continued until December 20th. The attacks of pleuro-pneumonia were treated by counter-irritation of the thorax, and quinia, carbonate of ammonia, with the addition of morphine.

The immediate cause of death in the three cases was, I believe, by thrombus of the cerebral veins or sinuses, the intimate connection of the pterygoid plexus with the facial vein, also the connection of the ophthalmic vein with the angular vein, a continuation of the facial, and the vein passing from the internal surface of the nasal cavities up through the foramen cæcum to the longitudinal sinus, the pterygoid veins and ophthalmic veins emptying into the cavernous sinus. Mr. H., Mr. R., and Mrs. H. became rapidly comatose, had stertorous breathing, and complete paralysis before death, all symptoms of compression of the brain. Billroth reports a case of death from malignant pustule, in which the post-mortem examination showed thrombus of the temporal veins, which was traced to the ophthalmic, and through the ophthalmic to the brain. Bartholow gives as the most frequent cause of sudden death in erysipelas of the face and head thrombus of either the longitudinal, cavernous, or lateral sinus.

"In cases of malignant pustules rigor mortis usually sets in early and passes off quickly; the body is often cyanosed; the face may be swollen; petechiæ on chest and abdomen are not uncommon; decomposition usually sets in early. The blood is generally dark, lake, and tarry, and in the heart often uncoagulated; the subcutaneous cellular tissue of the parts affected is hæmorrhagic, and hæmorrhagic patches radiate into the surrounding tissues, which are extensively infiltrated with a semi-gelatinous blood-stained fluid. In the pulmonary and gastro-intestinal form other anatomical characters are observed.

"The most important point in the microscopic anatomy is the presence of the bacillus anthracis in the blood and tissues, either diffused or forming masses in the lymphatics and vessels; the bacillus anthracis, as seen in the blood, consists of a motionless, short, apparently homogeneous rod or filament, rarely less than $\frac{1}{2500}$ of an inch long, either straight, curved, or bent at an acute angle. The usual mode of multiplication in the blood is by transverse fission. The bacillus anthracis requires for its growth the presence of a nitrogenized pabulum and a supply of oxygen; its vitality is destroyed by a temperature of 60° C.; when dry the rods themselves can be preserved but a short time, while the spores retain their vitality for years and are unaffected by ordinary changes of climate or temperature."[1]

The bacillus anthracis is a bacterium, first discovered by Pollender in 1849. All parts of the bodies of animals dying of the disease are actively poisonous, and may convey the disease by direct or mediate contagion; it may arise from eating the flesh, though the poison is said to be destroyed by cooking; contagion may also be conveyed by butter or milk. The bites of flies may also convey the poison. Contagion occurs in those who have to deal with the wool or hair of animals which have died of the disease, such as wool packers and sorters, horse-hair cleaners, farriers, tanners. The poison may enter the system either by local inoculation or by inhalation of the dust containing it. The diffusion of the poison by water and its distribution by means of wool-waste and bone-dust, used as manure, especially deserve notice, as capable of spreading the contagion.

"In the earlier stages diagnosis is very difficult, except in persons who are known to be exposed to contagion. At a later stage the characteristic features of the pustule render the recognition comparatively easy, and microscopical examination of the serum contained in the vesicles shows the presence of the bacillus anthracis. Inoculation experiments on guinea-pigs or mice will, if successful, readily decide it, but no absolute conclusion can be drawn from failure to inoculate.

"The prognosis is extremely unfavorable."

RETAINED PLACENTA.[2]

BY O. W. DOE, M. D.

IN 1861 Mr. Priestley communicated to the Obstetrical Society of London a paper on the Treatment of Cases of Abortion with Retained Placenta, urging manual interference if the placenta be retained longer than six hours, and earlier should hæmorrhage occur to any unusual extent. In this opinion he was seconded by such men as Dr. Tanner, Dr. Hall Davis, Dr. Tyler Smith, and others.

Since that time this question has been very much discussed, and recently as great a diversity of opinion regarding the treatment to be followed has existed in those cases where the placenta and membranes are not expelled with the fœtus as has lately been shown in the New York Academy of Medicine regarding the nature and cause of puerperal fever.

Drs. Mundé and Alloway advise either manual or instrumental removal of the secundines immediately after the expulsion of the fœtus in every case where the cervical canal is sufficiently patulous to permit the introduction of the finger, curette, or placental forceps, while Dr. Sweringen, with others prominent in the Indiana State Medical Society, prefer to leave its expulsion to the forces of nature, excepting in cases where some emergency demands its immediate removal.

Two years ago Dr. Warren, of Portland, read a paper upon this subject, in which he urged immediate removal of the placenta and membranes, as recommended by Dr. Mundé, and produced, in substantiation of this method of treatment, letters from Drs. T. G. Thomas, Lusk, Mary Putnam Jacobi, and others

[1] Greenfield.

[2] Read before the Boston Society for Medical Improvement, April 28, 1884.

equally prominent, who strongly advised this procedure. In the discussion which followed Dr. Gordon expressed himself as decidedly opposed to the advisability of forcible extraction, and reported a case where attempts to remove the placenta failed, and six weeks later it was expelled without any trouble resulting from its retention excepting an occasional slight hæmorrhage.

Dr. Coles, of St. Louis, has recently read a paper before the Obstetrical Society of that city purposely to controvert the views of Drs. Mundé and Alloway, and styles the doctrines inculcated by them as "dangerous in their tendencies" and "too dogmatic and sweeping in character." The tone of the discussion which followed favored a more conservative method of treatment, in so far as instrumental interference was concerned.

The treatment which I follow in my own practice is to attempt its manual, though not forcible, removal at once, as soon as the fœtus is expelled; if unsuccessful to tampon and wait from twenty-four to forty-eight hours. If retention still exists, to etherize and remove it manually, or instrumentally if necessary, as the danger of septicæmia seems to me much greater than that arising from its forcible removal carefully performed, and followed by antiseptic injections.

While this subject is at present so openly disputed by the most prominent members of the profession, I thought it might be interesting to the Society to hear the report of a case which was left entirely to nature, this conservative action arising from an error of judgment rather than from being an intentional act.

Mrs. G., aged twenty-seven, a lady of delicate and rather nervous organization, was last unwell from the 18th to the 22d of September, 1882. The catamenia began at the age of fourteen, and had always been regular. On the second and third Sunday in October she fainted in church, and during the third week of that month first began to suffer from nausea.

Her husband was taken ill on the 15th of January, and she was not only very anxious about him, but overexerted herself in going up and down stairs.

On the 17th the catamenia appeared, as she supposed, but the flow was very slight, hardly sufficient to soil one napkin, and the only pain attending it was an occasional sharp pain above the pubes, producing a sensation as if something in the back passage was pressing against the front. She remained in bed ten days, and was positive that nothing passed away from her during that time. Two days after getting up and going down stairs the flow began again, and continued at intervals for five weeks. At times it was quite profuse, but no clots passed away, and there was no pain, with this exception, that four days after the hæmorrhage commenced she was quite constipated, and took a large hot enema, and when this operated the pain low down in her back was so severe that she asked the nurse to press firmly against it. She was not conscious of anything having passed from the vagina.

I saw her in consultation on the 15th of March. At that time there had been no flowing for a week. She complained of feeling continually as if there was a heavy weight in the pelvis, and said she could not lie on her abdomen, as was her custom when well. This weight she could feel move when turning from one side to the other.

From external examination there was nothing abnormal to be detected in the hypogastric region. On vaginal examination the os was very small, and did not appear as if it had been previously dilated; the cervix was of usual length, and directed more anteriorly than normal; in the posterior cul-de-sac was felt a small body which I took to be a retroverted uterus, very sensitive on pressure, and quite freely movable. As she was very nervous and debilitated from her long confinement to the house, I thought it best to defer any attempt at replacement until her general condition was improved by tonics, and the sensitive congested body of the uterus relieved by hot vaginal douches. She steadily improved under this treatment, and was soon out driving. On June 23d she was taken unwell, as she supposed; the flow continued for a week, though very scanty, being dark and slightly offensive in character. Examination a week later showed the body of the uterus to be very much less sensitive and less easily reached, and though the patient was feeling quite strong, and had come by rail twenty miles to my office, she yet complained of this heavy weight in the pelvis. On the 11th of July she went to Concord, N. H., and there drove about almost daily, and improved greatly. On the 8th of August she was again taken unwell, and returned to Boston during the day. During the afternoon of the 9th she began to suffer from severe paroxysmal attacks of pain in the hypogastric region, which continued until evening, when they became expulsive in character, and at eleven P. M. a placenta was expelled, in size corresponding to at least three and a half months of pregnancy. There was but little hæmorrhage, and her convalescence was rapid and uninterrupted.

In summing up the facts in this case we find that she was last unwell on September 22d. She must have conceived soon after, as she fainted on the 8th of October, and began to suffer from nausea soon after the 15th. Her flow first began on the 17th of January, but she had no pain whatever until the 2d of February, when she had a severe pain in her back, while having a very constipated movement of the bowels. She was not conscious at the time of anything passing from the vagina, and the flow was not materially increased. With this exception she had no pain until August 9, 1883, when the placenta was expelled, being ten months and nine days from her probable conception, and one hundred and eighty-eight days from the date when there was the only possible chance of the fœtus having passed away.

The questionable mistake made, as subsequent results proved, was in not dilating the cervix and exploring the uterus at the time I first saw her in March. As it was then doubtful whether she had really been pregnant, and the uterus being so extremely sensitive, I thought it best to defer operative interference. The possibility of a retained placenta seemed hardly tenable, as we could get no history of a fœtus having been expelled, and we were positive in our convictions that pregnancy did not then exist, it being nearly seven months since the catamenia appeared regularly in September. Evidently at the time the abortion took place the placenta was adherent throughout, otherwise there would have ensued decomposition of the detached portion with possible septic poisoning and a more profuse hæmorrhage, and consequently any operative interference at that time would have been necessarily hazardous.

Dr. Mundé, among other indications which should induce the practitioner to forcibly remove the placenta, mentions hæmorrhage (without qualifying its ex-

tent). The case I have reported, as also that of Dr. Gordon, shows it may not be necessary excepting when when the hæmorrhage is profuse.

The degenerative changes which lessens the placental attachment to the uterus nature was slowly and safely instituting, and consequently even had I been cognizant of the placental retention I should not have considered myself justified, in view of the very sensitive condition of the parts, in dilating the cervix and curetting the uterus at the time I first saw her, as the danger thereby, it seems to me, would have exceeded that which the more conservative method followed subjected her to.

Dr. S. L. Jepson, of Wheeling, Virginia, in the *Journal of Obstetrics* for 1883, reports two cases of retained placenta, one of sixty-six days and the other of one hundred and fifteen days. He remarks that this latter period was the longest he had been able to find recorded. In each of these cases the placenta was removed instrumentally at these times, interference being necessitated by alarming hæmorrhage. In the case of longest retention the placenta was removed by forceps and curette after great difficulty. Eighteen months later she died twenty minutes after being delivered at full term, by turning.

Although there was no autopsy, Dr. Jepson thought it possible that death was caused by a rupture of the uterus due possibly to damage inflicted at the time of the removal of the placenta, as there was sudden collapse, after long continued violent uterine contraction, and immediate recession of the head followed.

RECENT PROGRESS IN PATHOLOGY AND PATHOLOGICAL ANATOMY.

BY WILLIAM F. WHITNEY, M. D.

THE MICROCOCCUS OF PNEUMONIA.

Mendelsohn [1] has brought together the principal facts which have gradually accumulated, and which point towards the infectious nature of pneumonia. These show that the disease appears with a certain typical frequency at different seasons of the year, just as intermittent fever, typhoid, or other infectious diseases. This distribution does not correspond with a more frequent occurrence during the colder and less frequent during the warmer seasons; further, some localities are attacked at times with the greatest virulence, while neighboring places having the same climatic conditions are exempt; and finally, hot and cold regions are visited equally. "Catching cold" as an exciting cause can almost always be excluded when the histories of the cases are carefully considered, and is an ætiological factor of the patient's own assumption. The method of onset and close are entirely different from those observed after taking cold. While these last begin gradually, pneumonia sets in suddenly with a severe chill. The termination differs still more markedly. The high fever drops within a few hours to under the normal, and the patient, who has been very sick up to this time, rejoices in a feeling of well being.

The direct proof of this suspicion, aroused by clinical observation, is given by the discovery of the constant presence of a form of micrococcus in the lungs.

Klebs was the first to characterize this as a parasitic affection, and he described as monas pulmonalis a micrococcus which he found in the hepatized lung, carefully freed from bronchial mucus, of a person recently dead. These were often to be seen in great numbers, and often so infrequent that they were only to be distinguished by other granular masses by being arranged in rows. In fresh preparations a quick movement was noticed. The same organisms were also found in the fluid in the ventricles of the brain. This author likewise called attention to the epidemic character of the disease.

Eberth next demonstrated the parasite in a case of pneumonia complicated with meningitis. Small, slightly oval or round bodies were found in the richly cellular and fibrinous exudation of the gray hepatized portions of the lungs, as well as in the purulent and fibrinous layer on the pleural surface. In part these were single balls, but the greater number were united in pairs, and had a gentle movement among themselves. Long chains or columns were never seen.

Koch has published the appearance found in a case of fatal pneumonia, which, however, is not to be regarded perhaps as of a pure type, as it occurred as a sequel to recurrent fever. The distribution of the parasites in this case recalled that of those found in erysipelas. The micrococci were only found in the alveoli adjoining the hepatized portion, and most abundantly in such as were only partially filled with an exudation. As in erysipelas, the living organisms surrounded the centre of disease by only a narrow zone. Similar bacteria were also found in this case in the capillaries of the kidney. They lay in the vessels united together in chains, but clearly showing their oval form.

The clearest description, and the most convincing proof of the connection of these organisms with the disease, has been furnished by C. Friedlander.[2] The cocci are of ellipsoidal forms, their length equals almost a micro-millemetre, their breadth about one third less; they are usually joined together in pairs (diplococci), but often form longer chains. In the fibrinous coagulations in the bronchi they are spread over a considerable surface in a flat layer. They are most abundant in the reddish-gray infiltration, less so in the yellowish-gray and gray hepatization. In one case the lymph channels of the interstitial connective tissue which lay on the boundary of the hepatized territory were filled to such an extent as to cause varicose swelling of the walls. The vessels thus filled could be distinguished by the eye in preparations cleared up by acetic acid, as silver-colored lines.

The method which he has used to show the presence of the parasites is as follows: Small portions of the hepatized lung are hardened in alcohol, and thin section made. These are colored by staining deeply in an aniline water solution of gentian violet. (Gentian violet, one gramme, aniline water (made by simply shaking aniline oil in water and then filtering) fifty grammes.) Afterwards the sections are placed for a short time in a weak watery solution of liq. iodinii comp. Upon placing in oil of cloves the blue color is discharged from the ground substance and nuclei of the tissue, while the micrococci appear in contrast, intensely colored. The author lays great stress upon the presence of a "capsule" as characteristic of this particular parasite. This presents itself as a feebly-colored belt of the same form, and from two to four times as broad as the micrococcus itself, and sharply bounded on

[1] Zeitschrift f. klin. Med., Band xvii., s. 178.

[2] Fortschritte der Medecin, November, 1883.

its outer edge. Diplococci and chains of three or four are inclosed in a common capsule, which then has an elongated form. Different micro-chemical tests warrant the conclusion that this capsule consists of mucin or a closely allied substance. The search for analogous capsules in micro-organisms of other origin has been for the most part negative. On the other hand, similar micrococci with capsules have been found in the pleuritic and pericardial exudation occurring in pneumonia, in the serous infiltrated adhesions, and in the simply œdematous parts of hepatized lungs. These were not found in the blood and other organs, and at times in inflamed lungs, where the process had existed longer than six days. The formation of the capsule appears then to be an attribute of the pneumonia coccus when it has reached the height of its development.

For purposes of cultivation outside of the body a preparation of gelatine, to which an infusion of meat with peptone and salt had been added, furnished the best nutritive material. A minute amount obtained from a fresh lung, inoculated on such a soil with strict precautions, soon developed at ordinary temperature into a little button-like eminence of a dull white color; this penetrated downwards with a sharp point into the gelatine, giving a peculiar "nail-shaped" culture. Microscopic examination showed this to be composed of elliptical micrococci thickly laid together. Capsules were only found surrounding a few of the single cocci. The gelatine did not become fluid with the older growth. The parasites could be made to grow on blood serum and potato, and their infective properties were proved by the inoculation of animals.

A portion of one of the cultures on gelatine was emulsified with water and injected by means of a syringe through the thoracic wall of nine rabbits, thirty-two mice, eleven guinea-pigs, and five dogs. The rabbits were entirely refractory, as were four of the dogs. On the other hand, thirty-one mice died in from eighteen to twenty-eight hours, one mouse in forty hours. At the autopsy in all these cases there was found a typical picture: a dirty red slimy fluid in the pleural cavity, the lungs almost entirely without air, with numerous foci of reddish infiltration. Micrococci were found in the pleuritic fluid, as well as in the blood even while circulating, which presented all the characteristics, especially the capsule formation, of the microbia of pneumonia. In the control experiments made with indifferent fluids injected in the same manner either the mice remained unharmed or died from other accidental causes. Six of the eleven guinea-pigs died, three in from twenty-four to forty-eight hours, three after a somewhat longer interval. In these there was found a double purulent pleurisy reddening and œdema of the lungs (three times red, reddish-gray, or gray infiltration).

In the lungs, and the foci of infiltration in them, at times only very few or no micrococci were to be met with. On the other hand, these were very numerous in the fluid from the pleural cavity, and could easily be cultivated. The micrococci with capsules were found very sparingly in the blood of two guinea-pigs. The five animals that remained unharmed showed themselves as entirely free from the micro-organism.

Experimentation by means of inhalation was made upon mice, and of these some were attacked by a typical pneumonia or pleurisy. In regard to the identity of the pneumonia coccus in the different kinds of animals, the size of many of the parasites in the mice greatly exceeded that from man. The cocci of the guinea-pig are smaller, but marked by an exceedingly broad capsule. In the dog they are hardly larger than in man, the capsule being but little broader than the organism itself.

Emmerich [1] has traced the cause of an epidemic of pneumonia which occurred in the prison for males at Amberg to a local infection of the dormitories. He was led to suspect that the refuse building material used to fill between the floors might harbor the parasite. He accordingly sowed minute fragments of this on gelatinized beef extract with peptone, after the method of Koch and Loeffler, spread upon glass slides.

After three or four days different kinds of fungi could be distinguished springing up. The gelatine was then rendered fluid by melting, and small quantities (one fourth to two cubic centimetres) were injected through the thoracic walls into various animals (rabbits, guinea-pigs, and mice), also into the blood of the first named. The animals died in from twelve to thirty hours. In the guinea-pigs the lungs were dark red; in the rabbits clear red; the spleen much enlarged. On the gelatine cultures as well as in the blood and organs of the animals there were found, besides various septic bacteria (especially the bacillus of malignant œdema), the peculiar encapsulated micrococci of pneumonia.

The cultivation on sterilized slices of potato seemed to this author to give a most characteristic growth. On this they developed in a yellow, slimy layer several millimetres thick, which had the peculiar property of always remaining moist. The capsules were found upon the cocci grown upon gelatine, while they were wanting where blood serum was used.

The anatomical appearances of the infected animals were characteristic.

All the mice and one half the number of guinea-pigs (in all about fifteen and twenty-five respectively) died in from twelve to thirty hours after the injection. Within two hours the breathing became deeper, and dyspnœa set in, which increased with the weakness until death.

Control experiments were made by using other pathogenic fungi in the same way. Circumscribed infiltrations of the lung were observed, but never well marked lobar pneumonia.

These experiments show the identity of the micrococcus of pneumonia and that found in the filling between the floors, where they must have existed in great numbers. The cracks between the boards gave exit to them, and thus they were widely distributed about the room.

In ordinary soil a similar coccus is found, but which grows differently on the prepared gelatine. In the space between the floors of houses where there had never been an epidemic of pneumonia the parasites could not be detected.

Should future investigations confirm these facts they will go far towards clearing up the ætiology of this disease in one of its essential points, namely, its occurrence as a house epidemic.

THE IDENTITY OF THE MICROCOCCI OF THE PNEUMONIA OF MAN AND OF THE CONTAGIOUS PLEURO-PNEUMONIA OF CATTLE.

Poels and Nolen [2] have examined the lungs of animals who have died from the above disease, and found numerous micrococci with the characteristic capsules.

[1] Allgemein. med. Central. Zeit., 1884.
[2] Centralblatt f. d. med. Wissensch., 1884, No. 9.

These presented themselves as mono- or diplococci, or as longer chains composed of several individuals.

Culture experiments were started at the same time on blood serum, material from human lungs and from animals being sowed. The result showed that the micrococci which came from these two sources developed into the characteristic "nail-shaped" growth when kept at the same temperature. Further inoculations were made from these pure cultures. Here, also, the results were identical. From these facts the authors believe in the identity of the organism which causes the disease.

THE ÆTIOLOGY OF ASIATIC CHOLERA.

During the past year a commission has been appointed by the German government to investigate the causation of cholera, and the results are embodied in letters written by Dr. R. Koch,[1] the head of the Commission. The first investigations were made in Egypt, but as the epidemic had almost subsided there the scene of their labors was shortly afterwards transferred to India, where the pest still raged.

On account of the great number of bacteria normally present in the intestine, it was very difficult at first to determine whether there was only one which was to be considered as associated exclusively with cholera. In the majority of cases death does not occur at the height of the process, but in the stage of reaction. At this time such marked changes appear in the condition of the intestine and its contents that it is impossible to obtain a clear idea of the lesions of the disease. It was not until a series of uncomplicated cases had been studied at autopsies that the real pathological relations could be determined, and then the greatest care had to be exercised in regard to the causal connections.

As the result of such examinations there has been found in the walls of the intestine of cholera patients a bacillus which can certainly be differentiated from all others by the following characteristics: The rods are never entirely straight, but curved a little like a comma, and can even assume a half-circular form. In the pure culture these curved rods often combined into S-shaped figures, and more or less slightly wavy lines. They possessed independent motion, which was very lively, and could be best seen in a drop of salt solution suspended from a cover glass. In a preparation of this sort the bacteria are to be seen swimming in all directions in the field of the microscope.

Their relation to nutritive gelatine is also very remarkable. At first they form colorless, transparent colonies, resembling small bits of broken glass. Gradually these liquefy the gelatine, and then spread out to a moderate degree. In this way they can be readily distinguished and isolated from the other bacterian growths. They can also be cultivated in hollowed object glasses, and accumulate on the edge of the drop of nutritive fluid, where they are clearly marked by their comma-like shape and rapid movements.

Up to the present time opportunity has been afforded for the examination of twenty-two bodies and seventeen cholera patients. In all of these the peculiar-shaped bacilli could be found both in the microscopic preparations from the subject and from the gelatine cultures.

This result, taken in connection with that obtained in Egypt, justifies the conclusion that these bacilli regularly occur in the cholera intestine.

[1] Allgemein. med. Central. Zeit., March 15, 1884.

In order to control this, twenty-eight other bodies were examined, eleven of which were of patients who had died from dysentery, the discharges from simple diarrhœa as well as from a person who had recovered from cholera, also the intestines of healthy and diseased animals, and finally water rendered foul by putrid masses, stagnant water from swamps, and scum from the surface. In not a single instance could the bacillus of cholera be found.

Since poisoning with arsenic gives rise to analogous symptoms a series of experiments on animals were instituted, but with negative results as far as finding the comma-shaped parasite.

The question then arises, In what relation do these peculiar organisms stand to the disease? Either these specific bacteria are favored by the cholera process, and are associated in such a remarkable way with its progress, or they are the cause, and the malady can only arise when these specific bacilli have found their way into the human intestine. The following grounds render the first supposition improbable: It must first be premised that a man who is ill with cholera must already have this particular form of parasite. But the bacilli are wanting even in intestinal affections like dysentery and diarrhœa, to which cholera is so often added. And it is hardly possible if they are normally present in every body, as the fact of their being found both in Egypt and India would tend to show, that they could have escaped observation up to the present time. Since, then, the growth of these bacteria cannot be produced by cholera, the second hypothesis alone remains, namely, that they are its cause. A number of other facts speak also for this assumption in a way not to be denied. Above all the relation during the progress of the disease. Their occurrence is entirely restricted to the organ which is the seat of the affection, namely, the intestine. In the vomitus they were but twice found, and then this had an alkaline reaction, showing that the intestinal contents, and with this the bacteria, had found their way into the stomach. In the intestine itself they deport themselves in the following manner: —

As long as the stools remain fæcal in the early stage of the disease only a few bacilli are to be found. On the other hand, the succeeding watery, odorless evacuations contain the specific bacteria in large numbers, while all the others have entirely disappeared, so that it almost amounts to a pure culture. As soon as the attack decreases and the stools again become fæcal the comma-shaped bacilli disappear gradually, and are not to be found after the restoration to health. The appearances after death correspond entirely with this. In the stomach nothing is found. The condition differs in the intestine, according as the patient has died during the proper attack or after it has ended. In the recent cases, in which the intestine is of a light red color, the mucosa free from extravasations, and the canals contain a whitish, odorless fluid, the parasites are found in enormous masses and entirely pure. Their distribution corresponds with the seat of inflammation, being most abundant at the lowest part of the small intestine. When death has taken place at a later period of the disease signs of marked reaction are manifest. The mucosa of the lower part of the gut is marked by dark-red extravasations, and often with a slight necrosis of the superficial portions. The contents are more or less colored with blood, and putrid and offensive from the reappearance of the bacteria

of decomposition. The specific bacilli are quite abundant in the tubular glands and the surrounding tissue, but not in the free contents. They are only entirely wanting in cases which have died from other diseases after the attack had passed off.

The cholera bacillus deports itself in the same manner as any other pathogenic bacterium. They occur exclusively in the disease to which they belong; their first appearance coincides with the beginning; they increase in number with the progress, and decrease with its decline. Their seat corresponds with the extent of the lesions, and their numbers become so great that the deleterious working on the mucous membrane can be explained by them.

It was greatly to be wished that an analogous disease could be artificially produced in animals. This has, however, not succeeded as yet, and to all appearances it is doubtful if it ever does. Yet the proof of the above-mentioned facts is not weakened by the failure of the experiments upon animals. In two other diseases, namely, typhoid fever and leprosy, specific bacteria occur which it is impossible to inoculate upon animals.

Moreover, the further study of the bacilli has brought out other characteristics which are of importance in this regard. One of the most remarkable is the repeated observation that the cholera bacilli increase in a remarkable manner upon the linen which has been soiled by the dejections of the patients and kept in a moist place for twenty-four hours. And in close connection with this is the clinical fact that persons who have to handle this soiled linen are especially subject to infection. Experiments were instituted by spreading some of the cholera dejections upon damp linen, filter paper, and earth. After twenty-four hours the slimy layer had regularly increased to a thick mass of characteristic bacilli.

This organism dies much more quickly upon drying than any other bacteria, three hours being sufficient to deprive it of all vitality. Further, the presence of an alkali is always necessary for their growth. Even a little free acid which did not markedly hinder other bacteria kept these back in their development. In a stomach which acts normally they are killed, and this is further borne out by the fact that neither in the stomach nor intestinal tract of animals which had been fed on cholera dejections could these organisms ever be detected. This last peculiarity, together with the readiness with which they are killed upon drying, gives a clew to the fact that infection so seldom occurs from immediate contact with cholera patients. Especial circumstances must be brought up to enable the parasite to pass the stomach and set up the cholera process in the intestine. Perhaps it could do so if the digestion was disturbed. And it is a well-known fact that men who have digestive disturbances are the most apt to sicken during an epidemic. Perhaps, also, there is a condition of the bacillus analogous to that of the reproductive spores of anthrax, but which up to the present time has not been discovered.

Still further proof of the rôle which the specific bacillus plays has been presented by Koch[1] in an account of a local epidemic of the disease which occurred near Calcutta, and which could be directly associated with the presence of the parasite in a contaminated tank.

It is the custom of the country for a number of families to use a common tank (which is merely a little pond or swamp-hole) for all the domestic purposes of washing and drinking water. The edges of the tank are often lined by privies, the contents of which are not prevented from contaminating the basin.

A local epidemic was reported to the Commission as having broken out in the neighborhood of one of these places. Samples of the water were immediately collected and sown upon nutritive gelatine; a development of bacilli corresponding in character with the specific organisms was developed, but with the decline of the epidemic such cultures were not to be obtained. Investigation showed that the tank had been used for washing the linen of a cholera patient, and the water had been contaminated in this way. Koch regards this in the light of an accidental experiment upon man, which is to be considered of the greatest value, especially since other animals have been found refractory to the disease.

Reports of Societies.

PROCEEDINGS OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M. D., SECRETARY.

April 28, 1884. The President, Dr. Charles D. Homans, in the chair.

PSEUDO-MEMBRANOUS ENTERITIS.

Dr. O. W. Doe showed a specimen of membrane which was passed by a patient suffering from pseudo-membranous enteritis, one portion being twenty-seven inches in length. This case, which is still under treatment, will be reported at a subsequent meeting of the Society. It appears similar to those reported here by Dr. Goss three years ago.

REMOVAL OF FŒTAL BONES BY RECTUM.

Dr. Doe also showed a collection of cranial bones of a fœtus at about the seventh month, which he had removed through the rectum three days before. The patient was last pregnant ten years ago, and had supposed that she miscarried at that time. The case will be reported in full later.

Dr. J. P. Reynolds inquired if the anus was lacerated in removing these bones.

Dr. Doe said that it was not. On the contrary it was very dilatable, and, being stretched by the fingers, the bones were worked from side to side with the forceps.

Dr. S. G. Webber read a paper on

MULTIPLE NEURITIS,

showing microscopic sections. The report of the debate is delayed by request of Dr. Webber.

Dr. O. W. Doe read a paper[2] on

RETAINED PLACENTA.

Dr. C. Ellery Stedman said that the treatment of retained placenta after abortion had to be left to each physician's judgment. His own experience left him in no doubt that as the placenta had to come away with more or less hæmorrhage, sooner or later, the proper plan was to avoid danger by removing it from the uterus as early as possible. The risks were from septicæmia and bleeding. He had seen two deaths after abortion from the former cause, though he did not recollect any fatal cases from loss of blood, yet

[2] Vide page 436 of this number of the Journal.

patients were often much reduced, and long in convalescing. Books tell us the finger is the best instrument for removal of the placenta, but do not instruct that for this purpose the hand has generally to be introduced into the vagina, which often necessitates ether. Sometimes a stiff wire doubled into a blunt hook was a help. The use of tents after abortion was to be avoided if possible, as it is fraught with danger, and, if for this reason only, he liked to empty the uterus as early as it could be done.

Dr. Francis Minot thought the proper treatment of retained placenta after abortion would vary according to circumstances. In recent cases it was sometimes difficult to determine whether the placenta or portions of the ovum were really retained or not because the clots were not preserved for inspection. In case of doubt it is best to wait for a day or two before exploring the interior of the uterus. But in case of continuous hæmorrhage, and especially in that occurring at intervals for weeks or months, no time should be lost in emptying the womb. He had rarely had any difficulty in doing this with the finger if the woman be etherized and placed on her left side, close to the edge of the bed, with the knees drawn upwards. Then the physician, pressing the fundus downward with the left hand over the pubes, and introducing the right hand into the vagina, can make the forefinger or the middle finger of the same hand meet the fingers of the left with only the uterine and abdominal walls between. In very fat women we sometimes fail to reach the fundus, and then the only resource is to fish for the placenta with long forceps, a tedious and difficult operation.

ETHERIZATION BY THE RECTUM.

Dr. Abner Post reported three cases at the Boston City Hospital. The *Boston Medical and Surgical Journal* of April 17th had a short account of etherization by the rectum as done at Lyons. Its administration in that manner has been tried at the City Hospital since that publication.

The ether has been given from a small bottle with a perforated cork, to which is attached a rubber tube, to the other end of which is fastened a catheter. The bottle of ether is placed in a vessel of warm water, and the catheter passed into the rectum. The ether is seen to boil in the bottle, and its vapor is conveyed through the tube into the bowel. The hot water used was drawn from the hot-water pipes, and was so hot as to be uncomfortable to the hands.

The first case was a patient of Dr. Homans, a man with cellulitis of the arm, who had been vomiting before etherization. After the tube was introduced he first complained of the taste of ether in the mouth. It was then noticeable to the by-standers in his breath. His pulse grew rapid, the pupils dilated, he partially stiffened out, put his hand to his mouth, vomited, and anæsthesia was complete at the end of thirteen and a half minutes. The ether was discontinued almost as soon as he was insensible, but the anæsthesia continued for nearly thirty minutes, probably not so complete as to allow surgical interference without shrinking during all that time, but so complete that he lay without motion. During the afternoon he had two or three loose discharges, mostly gas, for which he received a starch and opium enema, and which soon ceased.

The second case was a woman of large size, who had eaten a hearty breakfast before coming to the hospital. She took an ounce and three quarters of ether, and was insensible for thirty-four minutes. During the etherization the ether was administered evidently faster than absorption took place, as her abdomen became sufficiently distended to embarrass respiration; but a little pressure on the abdominal walls caused the gas to issue from both ends of the abdominal tube, and all difficulty ceased.

On recovering this woman vomited perhaps an ounce of thin, yellowish fluid. Within an hour had a natural movement of the bowels, and afterwards two slight loose operations, one of which was tinged with blood.

The third case was in every way a most favorable one except in length of time required to produce insensibility. The ether was given more slowly to avoid the distention of the bowels that had occurred in the previous case. A little less than two ounces was given, and etherization was complete in fifteen minutes. The stage of excitement was marked by a laugh and a comical remark or two, but no struggle. Insensibility continued nearly thirty minutes, and no unpleasant symptoms occurred during recovery. This patient was operated on for piles, and her rectum was packed with sponges to provide against hæmorrhage. Slight meteorism occurred, but no more than might well follow the closure of the anus. The sponges were removed after a few hours, but no diarrhœa showed itself.

So far as it is possible to draw conclusions from present experience, etherization by the rectum differs from inhalation principally by the absence, or rather the diminution, of the stage of excitement.

If vomiting occurs during the etherization it does not interrupt the administration of the anæsthetic.

The unpleasant after effects seem less marked. Vomiting, if it occurs at all, is slight.

The secretion of mucus, which so frequently fills the mouth and air passages, has not occurred so far. The spasm of the glottis which sometimes occurs at the commencement of inhalation, and which is the result apparently of the local effects of ether vapor, is not to be expected by this method.

The feeling of suffocation which is so common when ether is given by inhalation, and which is the cause of most or at least a large number of the struggles which patients sometimes indulge in, is wanting.

Of course the constitutional effects of ether, however given, are the same. The use of a much smaller quantity is sufficient to induce anæsthesia when given by the rectum, where all is absorbed, than when given by inhalation; at the same time the effect is slower in most cases. After complete anæsthesia is reached it is apt to grow more profound after the supply of ether has been removed — so that its administration should cease when once the patient is asleep.

The effect of ether upon different individuals varies very widely. It cannot be supposed that no patient will ever struggle if etherized by the rectum. Of course the man who makes a row whenever he is drunk will probably show his ugly disposition when ether is the cause of his excitement, but so far the excitement shown has been very small. The disagreeable effects seem to consist in the possibility of blowing up the rectum. Evidently the power of absorption differs in different individuals; probably the rate at which the vapor is poured into the rectum differs, as it ought to do, where the heat applied is indefinite and variable. It is necessary to watch the abdomen somewhat to see that it does not become ballooned.

An irritation of the rectum is set up in some cases which, perhaps, corresponds to occasional effects on the air passages when the ether is inhaled, but nothing so far has transpired to cause alarm or anything more than a temporary inconvenience.[1]

DR. WEBBER quoted the account of rectal etherization at Lyons, given in the *New York Medical Journal*, as stating that the process was finished by the mouth in some of the cases. He asked the experience of Dr. Post.

DR. POST thought the French surgeon must have been impatient. Etherization was profound.

DR. CHARLES D. HOMANS said that etherization was slower than in the common way. There was also much less ether used.

DR. POST said that there was less excitement as well.

DR. H. K. SABINE inquired if this method was used for the first time at Lyons, or had the Swedish surgeon who proposed it there seen it elsewhere.

DR. POST said that it was to be inferred from the published account that it had been done at Copenhagen.

NEW YORK ACADEMY OF MEDICINE.

THE TREATMENT OF MEMBRANOUS CROUP.

AT a meeting of the Obstetric Section of the Academy held Thursday evening, April 24th, DR. A. JACOBI read a paper on the medicinal treatment of membranous croup. Having repeated his assertion, made in 1868, that there ought to be no contra-indication to the performance of tracheotomy whenever, no matter how young the child or what complication might be present, there was danger of death from suffocation, and having stated that he had himself now performed it more than four hundred times, he said that he could hardly be accused of underrating the value of that operation (which had, indeed, already been discussed at a previous meeting) if he confined himself on this occasion entirely to the medical side of the treatment of croup.

He spoke first of the use of pilocarpine, and said that he had not modified the opinion which he had expressed in regard to it at the meeting of the American Medical Association in 1881, when he stated that in severe cases of septic pharyngeal and laryngeal disease he had found that this remedy actually hastened the fatal termination by inducing cardiac failure. He then mentioned two cases which had been under his care at the Mount Sinai Hospital, in which one of the children was a little over, and the other a little under, two years of age. Neither case was very severe, and the treatment consisted of the inhalation of steam with the vapor of turpentine, under a tent, and the use of pilocarpine muriate in one-thirtieth-grain doses after the manner of Guttmann. Under this treatment one of the cases got well, but in the other the pilocarpine had to be withdrawn after two days on account of its depressing effect, notwithstanding the fact that alcohol was freely used to counteract this. The final recovery in this instance was attributed, first, to the macerating effect of the pilocarpine on the mucous membrane, and, secondly, to the timely discontinuance of the drug. Dr. Jacobi also mentioned another case, three years ago, which recovered with a fair amount of strength after taking it for four days, and said that his final opinion in regard to it was that it was a powerful remedy, which was of considerable service in certain cases, but which, on account of its debilitating effect, had to be watched with great care, while at the same time its depressing influence was counteracted as far as possible.

In regard to the use of steam inhalations, his views, as expressed in his treatise on diphtheria published in 1880 (page 168), had not changed. In employing them it was not to be forgotten that by this agency the underlying tissues were also softened, and that the poison was thus sometimes enabled to penetrate more deeply. The results were not always satisfactory, and he had seen cases which became distinctly less cyanotic on being taken out of an atmosphere filled with steam. At the same time in many instances the steam was of great service, the benefit depending to a large extent on the special locality affected. Thus wherever there was pavement epithelium beneath the membranes it could not be employed successfully. He therefore again insisted that steam will improve; steam will impair. It was a matter of vital importance where steam inhalations were resorted to that the patient should also have plenty of fresh air.

He also repeated his conviction of the utility of the inhalation of turpentine, which he had first employed many years ago in cases of pneumonia where resolution and expectoration had not commenced. He recommended that about a tablespoonful of the rectified spirits or oil should be poured into water that was being heated over an alcohol lamp or stove or the gas every hour or oftener, and mentioned one case at the Mount Sinai Hospital in which a child two years old was kept, with its nurse, under a tent filled with steam charged with turpentine for four successive days and nights. No other treatment was used except the internal administration of chlorate of potassium and tincture of chloride of iron, and he believed that by this means the case was kept from being a severe one.

Dr. Jacobi then said he would select one topic for discussion in this connection which was not a new one, but which, in the light of recent developments, had excited renewed interest, and that was the treatment of croup by mercurials. In order that the subject might be discussed intelligently he first gave a very careful and complete review of the opinions of various authorities in regard to it from the time that Dr. Samuel Bard wrote, in 1771, down to the present. In regard to his own opinion concerning the use of mercury, in the treatise on diphtheria before referred to he had expressed himself as more favorably disposed towards it at that time (1880) than he had been in former years, and since then he had still further modified his views in the same direction. At the meeting of the American Medical Association in 1881 he had been particularly impressed by the remarks of Dr. William Pepper, of Philadelphia, in favor of the bichloride of mercury treatment. The latter, in the course of his address in medicine, said that his attention had been called to the matter by a paper read by Dr. G. A. Linn before the Pennsylvania State Medical Society, in which he reported a number of cases of pharyngeal and laryngeal diphtheria treated with eminent success with the bichloride, and that he had first used it himself in a case of diphtheritic croup which he saw in consultation with Dr. Yarrow, of Philadelphia.

[1] Further experience leads me to modify somewhat the favorable opinion here expressed. Certain feeble individuals have taken an unusually long time to recover, insensibility has been occasionally so profound as to cause anxiety, and bloody discharges have been more frequent than is desirable. A. P.

The child, at the time the remedy was commenced, seemed actually at the point of death, and the recovery appeared to him nothing less than miraculous. Dr. Jacobi then went on to say that although he did not claim to be one of those "who never lost a case," he had found the treatment by bichloride of mercury very satisfactory as a rule. He recommended that it should be given very largely diluted (about one grain to the quart of water) in order that gastric and intestinal disturbances might be avoided. Having mentioned the great superiority as an antiseptic of this agent to all others that had yet been discovered, he referred to a paper published by Dr. William Thallon, of Brooklyn, in the *New York Medical Journal* for April 12 and 19, 1884, in which he reported ten cases successfully treated with the bichloride.

The last part of the paper was devoted to the treatment of the patient after tracheotomy had been performed, after which he summed up his conclusions as follows: —

(1.) The mercurial treatment of membranous croup is promising of good results.

(2.) Corrosive sublimate is, as a rule, the best of the preparations of mercury for this purpose.

(3.) It should be given early, and the dose frequently repeated.

(4.) It should always be given largely diluted (about one to three thousand).

(5.) To infants half a grain should be given in the twenty-four hours, and this quantity may, as a rule, be kept up for a considerable number of days without any evil results.

(6.) Salivation and stomatitis are very rarely observed, and gastro-intestinal disturbances are not frequent from its use.

(7.) If any such disturbances should result mercurial inunction, preferably by the oleate of mercury, may be instituted for the bichloride.

(8.) If the case is taken in time the treatment for croup itself may frequently be prevented by the use of the bichloride when the croup is the result of descending pharyngeal diphtheria.

After the conclusion of the paper he referred to the details of three cases successfully treated with bichloride of mercury, which he said he had selected as samples out of a large number of others. The first was one which he saw in consultation with Dr. E. J. Hogan, in which the child was apparently dying from increasing obstruction after tracheotomy had been performed. The second, which was seen in consultation with Dr. Hanks, was a case of croup resulting from pharyngeal diphtheria, and the third, a desperate case of fibrous tracheo-bronchitis in an infant of five months, was seen with Dr. T. Herring Burchard, who read a minute history of it. In a few supplementary remarks Dr. Jacobi then said that within the last fourteen years he had never met with so many successful results in croup, either before or after the performance of tracheotomy, as during the past year, when he had largely depended on the bichloride of mercury.

DR. FOREST stated that two years ago he had a case of croup which grew worse steadily for four days, and was suffering from complete aphonia, when Dr. Jacobi, who had been called in consultation, recommended the use of one twentieth of a grain of bichloride of mercury every hour. Three doses of the drug, however, produced such marked tenesmus that the dose was reduced to one fiftieth of a grain, but the latter quantity was well borne, and the case resulted successfully. Since then he had tried the bichloride extensively, and, as a rule, had found that it acted surprisingly well. When he used steam inhalations he always employed Codman and Shurtleff's atomizer, which he thought was decidedly preferable to filling the whole room (the air of which should be kept fresh and at a temperature of about 70° F.) with steam, and he was in the habit of ordering a teaspoonful of listerine to be put in the water of the atomizer every half hour. Whether the antiseptic had any special effect or not on the disease he was unable to say.

After some remarks by Dr. JOHN C. PETERS, who stated that he was a strict localist (believing that in diphtheria the systemic infection originated by absorption from the diseased throat), and principally advocated the topical use of astringents and chlorate of potassium, DR. J. LEWIS SMITH spoke at considerable length on the mercurial treatment of croup. The seniors present, he said, would recall that a number of years ago calomel was in common use in this disease, and some of them would, perhaps, remember quite a noted case that occurred at the Astor House before 1858, when diphtheria was first recognized in New York. A child staying at that house was so seriously ill with membranous croup that several eminent physicians of the city said that it was impossible for it to live, when a practitioner from Albany, where the family resided, as a last resort, gave it twenty grains of calomel dry upon the tongue, after which, to the surprise of everybody, the case began to recover. A prominent medical man in New York at the present day believed that if a large dose of calomel were given at the onset of the attack it would favorably modify the course of the disease; but when diphtheria made its appearance in 1858 the profession were certainly disappointed in the effect of calomel, both in large and small doses, and it was found to produce so much prostration that the mercurial treatment was soon altogether abandoned here, except by a very few physicians. Now, however, there had commenced a revival of the use of mercury. As to the views expressed by Dr. Walton in the paper referred to, he must say that he failed to be convinced of their force. The cases that he reported had been cured by the supposed germicide effect of the bichloride of mercury, which was recognized to be the most powerful agent of this class known to science; but he doubted very much whether it was entirely safe to give corrosive sublimate in sufficient quantities to have a germicide effect upon diphtheritic poison in the system. It was believed that these antiseptic agents acted by being taken into the blood and destroying the disease germs which had found a lodgment there; but he could not but think that if this were the case they would have a destructive effect upon the economy itself, since these minute organisms were as tenacious of life as the corpuscles of the blood, and hence the latter would be destroyed at the same time.

Wherever the pseudo-membranes of croup were formed there was first the exudation from the blood (the fibrine), and, in addition, a collection of altered epithelial cells, as held by Rindfleisch and other authorities. Now as to the fibrine, it was acknowledged by all that it could be dissolved by alkalies, and in a series of experiments in which he had participated together with several other physicians connected with the New York Foundling Asylum it had been demonstrated that a two per cent. solution of liquor potassæ

was sufficiently strong for this purpose. With regard to the solubility of the epithelial cells entering into the composition of the pseudo-membranes by alkalies there was at present considerable difference of opinion, but this epithelial element was supposed to be analogous to *mucine*, and the latter was undoubtedly soluble in a weak alkaline liquid. He felt constrained, therefore, to adhere to his confidence in inhalations of medicated steam as a principal factor in the treatment of membranous croup, and the alkaline formula which he had found of the greatest service was a two per cent. solution of liquor potassæ in lime water to which a sufficient additional quantity of lime had been added to render it somewhat turbid. When in any case he found huskiness coming on he felt it his duty to resort at once to such inhalations, and if there was but a slight deposit of pseudo-membrane he believed it would be promptly dissolved by them. Another important advantage which he thought they possessed was that when there was an accumulation of muco-pus in the respiratory tract below the level of the membranes (which was a frequent additional cause of dyspnœa in croup), the mucus was dissolved by the alkaline vapor, and consequently the pus became thinner and more easily expectorated.

At one of the recent discussions on croup in the Section he had expressed the opinion that nothing of an irritant nature should be used by inhalation or in any other topical way. Since then he had noticed that a writer in one of the journals had advised the employment of such a caustic as nitrate of silver, and he thought it was the duty of the Academy of Medicine to protest strenuously against any procedure of this kind. This was the objection which he had to the bromine treatment which had been so highly lauded in diphtheria by one authority in this city, — it was too irritating. He had been more and more impressed all the time with the great importance of alcohol in the treatment, and said it was surprising to find what large quantities of it were often tolerated. Thus, it was not uncommon to see a child one year old taking with advantage as much as a teaspoonful of brandy or whiskey every hour. He stated, in conclusion, that he should be glad to make trial of Dr. Pepper's treatment with the bichloride of mercury, as indorsed here on this occasion; but so far as its advantages were shown in the cases reported by Dr. Thallon he did not feel altogether convinced of its efficacy. This was on account of the character of some of the cases, which the writer designated as croup when there was simple huskiness, without dyspnœa, present. If he (Dr. Smith) were to classify his own cases in the same way he would be able to report that fully one half of his cases of croup recovered under the use of alkaline steam inhalations. Again, in one of Dr. Thallon's cases inhalations of chloride of ammonium were resorted to, and he thought that possibly some of the good effects noted might have been due to this remedy, which was an alkali.

Dr. Jacobi said, in reply, that he thought it was not fair to confuse the calomel treatment with that by bichloride of mercury. The latter produced salivation less frequently than any other preparation of mercury. As to the destruction of the blood-cells, in addition to the bacteria in the blood, this was doubtless true of most antiseptic agents, if used in sufficient concentration to be efficient as germicides; but it had been demonstrated conclusively that it was not true in regard to bichloride of mercury. It had such an extraordinary antiseptic effect that a single grain of it was sufficient to destroy all disease-germs in the blood of a child of five years, which weighed about two and a half pounds. The poison could thus be completely eliminated without affecting the blood itself, since it had no injurious effects upon the corpuscles; and it was furthermore believed to be the only germicide which could get into the blood in an unchanged condition. It was at present undecided whether diphtheria depended on a micrococcus or not, but he would not discuss that question now. He looked on the bichloride simply as an antifermentative, and he had seen it produce some remarkable practical results. That was sufficient to encourage him to go on with its use, and he was content to wait for a theoretical explanation of its *modus operandi* that could be found correct.

In closing, he said he wished to lay stress again on the fact that when the bichloride was employed it should be given as early as possible and in frequently repeated doses. There were, as a rule, no bad results from it whatever, and in one or two cases he had given as much as a grain in the twenty-four hours. A child of five months should have at least half a grain in that time. Since he had heard of the tenesmus produced by it in the case which he saw with Dr. Forest, however, he had been careful not to have the dose too large, and he was always particular about having it very freely diluted.

NEW YORK COUNTY MEDICAL ASSOCIATION.

SCARLET FEVER IN THE FŒTUS IN UTERO AND IN THE MOTHER AT THE NINTH MONTH OF PREGNANCY.

This was the title of a paper read by Dr. Charles A. Leah at a stated meeting of the Society held April 21st. Scarlatina was so seldom met with in the fœtus in utero, he said, that several authorities of experience have denied that the disease occurred under such circumstances. Thus, J. Lewis Smith, in his work on diseases of children, stated that, while cases had been reported of scarlet fever occurring in the fœtus, and manifesting itself by the usual signs at birth, a clear diagnosis in such instances was necessarily difficult on account of the character of the scarlatinous eruption on the one hand and the nature of the cutaneous circulation in the newly-born on the other. In his opinion, therefore, in the cases alluded to there was probably an error of diagnosis. Prof. Theophilus Parvin, at a meeting of the Obstetrical Society of Philadelphia, held April 3, 1884, after giving an account of an outbreak of measles and scarlet fever in the obstetric wards of the Philadelphia Hospital, stated that while children had been born with measles, he did not know of such an experience with scarlet fever.

It had been his sad experience, however, to see an undoubted case of it in a child at birth during the time of an invasion by the disease of a young family, every member of which, with one exception, was attacked, and in which the wife and mother quickly succumbed before the violence of the onset in her case. The family consisted of the father, twenty-five years old, the mother, twenty-four years old, a son, four years old, and the monthly nurse, sixty years old, and the infection was introduced by a relative who came directly from a household where scarlet fever was raging,

and who, although she did not have the disease herself, was at the time suffering from the form of pharyngitis so often met with during the prevalence of scarlatina among those not attacked. At the time of her arrival also the little boy was affected with the ordinary tonsillitis of childhood. The father, who was the only one of the family known to have had scarlatina before, escaped; but all the others, including the aged monthly nurse, took the disease. The family until a short time previously had lived in the country, and, without exception, had always been remarkably healthy, living in a salubrious neighborhood, and being surrounded by the best sanitary conditions. When they came to New York, however, they occupied a dark and badly-ventilated French flat.

The mother, who was now at the end of the ninth month of utero-gestation, when seized with the scarlatina at once became alarmingly ill. In a few hours the eruption extended over her entire body, and at the same time she felt the most violent motions on the part of the fœtus, so that it seemed probable that it was in convulsions. The mother soon became delirious, and the whole situation appeared so critical that Dr. Leah decided to bring on active labor at once. The cervix readily yielded to digital dilatation, and in four hours he delivered with the forceps a male child weighing nine and one half pounds. He was gratified to find that the hæmorrhage incident to parturition was sufficient to relieve the existing cerebral congestion, so that the mother returned to consciousness, while the febrile and other symptoms were less urgent than before the birth of the child. The improvement continued for twenty-four hours, when the temperature began to increase again, and the skin assumed a dark purple hue. She then continued to grow steadily worse, and died fifty-six hours after labor. After death the body quickly underwent such changes as to render it unrecognizable.

The child, which was well-developed, was found to be unquestionably in the midst of the eruptive stage of scarlet fever. It made no effort at respiration, and rubbing it along the spine, placing it upon the side, and making alternate applications of hot and cold water to its body, had no effect in establishing this function until after the cerebral and hepatic stasis from which the infant was suffering was relieved by allowing about an ounce of blood to escape from the umbilical cord. In addition, the thickened mucus, which was clogging up the air passages and interfering with respiration, was removed by the finger and by suction; pressure was made intermittingly upon the abdomen, and flagellation of the nates was practiced. Notwithstanding all these efforts, however, it was fully fifteen minutes before the child breathed regularly, and it was so excessively weak it was wrapped in warm flannels for a considerable time before any attempt was made to wash it. For some days the whole surface of the body was covered with the eruption, the color of which was often very dark, and it then began to fade. At the same time the throat symptoms, which had been well marked (the mucous membrane of the mouth and fauces presenting the typical appearance, with the characteristic raspberry tongue, of scarlet fever), also commenced to subside. Desquamation began about the tenth day, and some of the masses of epidermis thrown off were an inch square. This continued actively for the next week, and during this period desquamative nephritis set in, as indicated by the condition of the urine, which contained about one tenth part albumen. General anasarca also resulted, and was first noticed on the fourteenth day. By the end of the fourth week, however, the infant had entirely recovered from the attack.

On account of the unfortunate results following the exposure of this family to the risk of contracting scarlatina, Dr. Leah thought it his duty to utter a solemn note of warning about the danger to parturient women from the contagion of this disease, and the urgent necessity for preventing the exposure of such patients to it in every possible way. He felt it the more important to do this from the fact that from time to time communications were published in which this danger was entirely underrated, and it was only that very day that he had read an article in the *Journal of the American Medical Association* for April 19, 1884, condensed from one in the *Practitioner*, which he thought likely to be productive of much mischief. In it the writer advanced the following points: —

"(1.) Cases have over and over again been reported where there have been cases of scarlatina, not only in the same house, but in the same room, and even in the same bed, with the parturient woman, without the occurrence of any ill effects.

"(2.) I have been credibly informed by a medical man that he was once called away from a case of scarlatina he was watching to attend two cases of midwifery, and that neither of the lying-in women had any unfavorable symptoms afterwards.

"(3.) I have also been told, and my informant is willing to swear to the fact, that one medical man attended three cases of confinement when his hands were freely peeling from scarlatina, and that not one of these cases had anything the matter subsequent to their confinement."

In connection with the above, Dr. Leah related an account of a soldier he had known of in the late war, who, during a battle, was left exposed between the fires of both armies, and yet who, although he actually received twenty-six bullet wounds, did not die. As well might one argue from this that the man was in a safe position, he said, as contend from the instances mentioned that there was no danger to the parturient woman from scarlatina. He maintained, however, that the cases of puerperal septicæmia in which there was a more or less well-developed eruption resembling that of this disease were not instances of true scarlatina.

As to the occurrence of scarlatina in the fœtus in utero there were now a number of well authenticated cases on record, both in this country and in Europe, in which the most strongly marked characteristics of the disease were found present upon the child at birth. At the same time many medical men of the largest experience had stated that they had never met with a single instance of it. Thus, Meigs and Pepper mentioned that the earliest age at which they had seen a perfectly well marked case of scarlet fever was twenty-one days. Vogel stated that very young children were not subject to the disease, but the statistics of Murchison showed that of 148,829 deaths from scarlatina in England and Wales in 1847, and from 1855 to 1861, no less than 9999, or about seven per cent., were in children under one year. In the city of New York, again, there were 734 deaths from the disease in the year 1883, and of these 67 were in children under one year. Voit reported the case of a child, born on October 3, 1856, who was taken sick with scarlatina on the

17th, after the brother, eleven years old, had been attacked with the disease on the 1st of October. Meynet told of a woman who, three weeks after the convalescence of her husband, and three months after the death of her child, from scarlatina, was delivered of a girl who was somewhat red when born; the redness becoming more intense on the following day, and the skin feeling very hot. These symptoms diminished after a few days, but again became more intense on the thirteenth day. On the fifteenth day Meynet noticed the well-developed redness of scarlatina on the whole body, the tongue and the palate; the tonsils were swollen, and there was fever and apparent difficulty of deglutition. On the seventeenth day the redness had almost entirely disappeared, and the general condition was good; but during the subsequent fortnight there seemed to be no desquamation, and this made the case somewhat doubtful. A case reported by Asmus was also doubtful, as desquamation frequently appeared even in healthy newborn children in whom there was no suspicion of scarlatina. It was as follows: A mother had lost two children towards the end of her pregnancy from scarlatina, and soon after her confinement became dropsical. In her new-born child, who was very much emaciated, the epidermis over the whole body separated in large sheets, and from the hands it came off like gloves; the infant afterwards recovering completely. Potier observed that a woman took scarlatina on the day of her confinement and died a fortnight afterward, and that her child, though isolated immediately after birth, became affected with intense scarlatina. Küpfer met with a scarlatinous patient two months old, Voit one two and one half months old, and Haller one five months old, while Fleischmann saw none under six, and Eulenburg none under eight, months old.

Prof. Louis Thomas, after stating that he had himself never met with the disease under the age of five months, went on to say that it was difficult to ascertain whether children were born with scarlatina, because the majority were born with a red or yellowish-red skin, which resembled the eruption of scarlatina, and was followed by desquamation; but as children were born of variolous mothers, or of women who during pregnancy had been exposed to the contagion of small-pox, and at birth had been found affected with the disease, he could not see why this should not also happen in the case of scarlatina. According to Noirot, Baillou, as early as 1574, established the occurrence of such cases, and Farrario had also published an undoubted case. According to Naumann, the latter saw several cases. Tortual reported the case of a woman, thirty years old, who had never had scarlatina, and who, after nursing her husband and son, who were sick with the disease during the eighth month of her pregnancy and up to shortly before her confinement, was delivered of a male child on the 19th of September, 1823, which could not swallow and had an uncommon redness of the skin. This Tortual did not hesitate to regard as the characteristic eruption of scarlatina, especially as the tongue and mucous membrane of the mouth, in addition, were of a glistening red color. The difficulty of deglutition continued until the fifth day, when the child drank eagerly, and on the ninth day abundant desquamation commenced, just as in older children. Later, also, a separation of the nails of the fingers and toes took place, but the child recovered completely. During an epidemic of scarlatina a son was born to Gregory on April 23, 1839, who was evidently suffering from some form of fever, and on the following day the child had a decided angina maligna, without an exanthem, as a result of which it emaciated and died on May 1st. Stiebel related that a woman, twenty-five years old, manifested a very abundant eruption of scarlatina towards the close of her pregnancy, and that after birth the child could not swallow, while its skin was of a scarlet-red color and desquamated in larger scales than usual. Hüter mentioned the case of a woman who, during an epidemic of puerperal fever, gave birth to a child affected with the most clearly marked scarlatina in the stage of eruption, the woman herself dying four days afterward of metrophlebitis. In the year 1828 Trousseau was appointed at the head of a commission to investigate a serious outbreak of scarlet fever in a rural district of France, which was especially fatal to puerperal women. In thirty-six cases the women were attacked within forty-eight hours after labor, and died in a few days, and one practitioner lost no less than nine of his lying-in patients. Ernst Wagner, of Leipsic, had expressed the opinion that the fœtus might be ill with such diseases as scarlatina and small-pox without the mother being affected.

Of late years, Dr. Leah went on to say, scarlatina had been increasingly prevalent and fatal in New York. During the twenty-five years before 1829 there were only 111 deaths reported from it altogether; but in the last three months of 1829 alone there were 124 deaths from it, an increase which caused much alarm among the citizens. During the last eighty years there had been 37,271 deaths from scarlatina in New York; but the slowness of increase in their number for a time was worthy of notice. In 1804 there were 14 deaths, but in the twenty years following there were never more than five deaths *per annum*. In 1824 there were but three deaths from it. During the past twelve years, however, there had been several severe epidemics of the disease, and in 1882 the mortality from it reached 2066. Hillier's statistics showed a mortality of 52,464 during the years from 1848 to 1866, and Meigs and Pepper stated that the number of deaths from it from 1809 to 1868 in Philadelphia was 13,116.

Although Dr. Leah had met with three cases of undoubted scarlatina in puerperal women, he had seen but one case of it in the fœtus, the one whose history he had related in detail. Two of the cases of puerperal scarlatina had occurred in his own practice, and the third in a patient of the late Dr. Peaslee, whom he had been called to see on account of the sudden onset of convulsions. The child died two minutes after birth from the accumulation of mucus in the air-passages, and the mother died on the third day afterward. He then stated that he had endeavored in vain to find at the New York Health Department any records of scarlatina occurring in pregnant and puerperal women or in the child at birth; but Dr. Naegle, the registrar of vital statistics, had informed him that during the year 1883 sixty-seven deaths from the disease were reported in children under one year old, and nineteen cases in females in the child-bearing period of life. Between the ages of fifteen and twenty years there were six cases; between twenty and twenty-five, four cases; between twenty-five and thirty, six cases; between thirty and thirty-five, two cases; and between thirty-five and forty, one case.

At a meeting of the Obstetrical Society of Philadelphia held April 3, 1884, Dr. W. T. Taylor stated

that he had had a case of scarlet fever in a mother which came on two days after labor, and proved fatal, though the child escaped. As a rule, however, Dr. Leah said, the disease was not nearly so fatal when it occurred after, as when it commenced before or during, labor. In one of the three cases to which he had referred the attack came on one week after the birth of the child (which escaped), and the mother recovered.

DRS. WILLIAM DETMOLD and J. W. S. GOULEY spoke of the condition of the kidneys in scarlet fever as rendering the disease peculiarly dangerous to the parturient woman (in whom there was usually considerable renal congestion and interference with the abdominal circulation), and, therefore, of immense interest to the obstetrician.

DR. DWYER said he had met with one case of puerperal scarlatina, in which the woman was seized with eclampsia and died at the moment that the child was born. He had also met with three cases in which pregnant women nursed children suffering from scarlet fever, but were not taken with it themselves, while the infants afterward born to them also escaped.

DR. W. T. LUSK thought it was a matter of great interest that women if exposed to the contagion of scarlet fever while pregnant rarely developed the eruption and other characteristic signs of the disease until the approach of labor or after the birth of the child; the period of incubation being unusually long, or the scarlatina poison remaining dormant in the system until the termination of utero-gestation. In scarlatina in parturient women the symptoms also generally differed in a marked degree from the ordinary type. Thus, the eruption and the fever often made their appearance simultaneously, and in a large proportion of cases there were no throat-symptoms; while many of the cases died before the manifestation of any kidney-trouble. That there was a scarlatinous rash due to septicæmia, and independent of exposure to the contagion of scarlatina, he had his doubts; and he had certainly never observed such a phenomenon himself, although he had had an unusually extensive experience with puerperal fever of various forms. As a rule, he had found that puerperal scarlatina was not associated with peritonitis or cellulitis. This disease was usually regarded as peculiarly fatal; but he was inclined to think that, as in the case of scarlet fever in children, the result depended a good deal on the general character of the epidemic prevailing at the time and the special circumstances of the individual case. Dr. Lusk then alluded to the investigations of Braxton Hicks, who had found that many of the cases of puerperal scarlatina closely resembled ordinary puerperal septicæmia, having none of the characteristic features of scarlet fever in general; and stated that in England instances had been reported in which children had contracted ordinary scarlet fever from such cases. No case of this kind, so far as he was aware, had as yet been reported in this country; and the records of the New York Health Department for nine years showed no proportionate relation between the number of deaths from puerperal fever and those from scarlet fever. Matthews Duncan had found the same thing true in London; but at the same time Braxton Hicks might still be correct in his views, the matter as yet not being definitely settled. Under any circumstances, however, he thought the practitioner of midwifery could not be too cautious, and that if in any case where he had gone from a scarlet fever patient to attend a confinement the result proved bad, the physician could not but reproach himself, whatever the woman died of. Any one who was skeptical about this matter would be likely to be very severely punished sooner or later, and there had been one or two cases in the earlier part of his own practice which had taught him a lesson that he would not be apt to forget soon.

DR. S. T. HUBBARD said he had had but one case of puerperal scarlatina in his practice. The disease, which was perfectly characteristic in its manifestations, did not come on till the third day after labor, and the patient died on the third day following the appearance of the eruption. The child also died when four or five days old. He was not able to trace the origin of the disease in this case. He had always made it a special point to refrain from attending lying-in cases when treating scarlet fever patients, and thought this was the duty of every practitioner of midwifery.

DR. C. S. WOOD was inclined to doubt the extreme danger to the puerperal woman of the contagion of scarlet fever. When the disease occurred in families of pregnant women who had never had it, he had formerly been accustomed to await the approach of labor with much anxiety, but his experience had convinced him that the danger had been exaggerated. Thus, a mother who had nursed a child suffering from scarlet fever for twenty-one days was confined ten days after the expiration of the twenty-one days, and passed through the puerperal period in a perfectly natural manner, while the new-born child also escaped contracting the disease. He had been engaged in the practice of medicine for thirty-five years, during which he had had a large experience with scarlet fever; but he had never seen a case in which the contagion was carried by himself.

Remarks were also made by several other members; after which DR. LEAH said that he thought there was a plain distinction between puerperal scarlatina and ordinary septicæmia; the evidence showing positively that scarlatina was not due to septicæmia. Thus, in the case of the family whose history was reported in the paper, the mother had scarlet fever before the child was born, the child was affected with the disease when delivered, and the monthly nurse contracted it. As to the susceptibility of puerperal women to get scarlet fever, he did not think this was very great, and this was due to their age, as well as to the fact that many of them had had the disease in childhood. But although it did not occur very frequently, the point which he wished particularly to impress was, the extreme danger of scarlatina when it was contracted during the puerperal state, and hence the great importance of preventing all exposure.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. W. SWAN, M. D., SECRETARY.

OCTOBER 13, 1883.

SEA VOYAGES AND AMENORRHŒA.

DR. CHADWICK reported cases.

DR. INGALLS suggested that the functions of other organs were equally liable to be disturbed by the voyage, which might, therefore, reasonably be expected to exert some influence upon the menstrual function, the regularity of which, he had reason to believe, was also not infrequently disturbed by long journeys by rail.

Dr. Brown said that he had seen at the City Hospital several cases of the kind cited by Dr. Chadwick, occurring mostly in the grade of newly arrived known as "assisted emigrants." He had learned to recognize, in the emigrant, the facies indicative of menstrual deficiency. The majority of these cases had been those in which the catamenia had been arrested during the voyage and had not returned, usually accompanied by constipation, anæmia, and general malaise.

Dr. Richardson said he could add his testimony to that of Dr. Chadwick, and that it was very common at the Massachusetts General Hospital to see young women with amenorrhœa which had apparently resulted from the voyage, as often when they had not been unwell on the voyage as when occurring and arrested during the journey. There were no symptoms of pregnancy; a few have had headaches and backaches, as in suppressed menstruation.

Dr. Lyman observed that a distinction should be made between those cases in which the function was normally performed and those habitually irregular before the voyage. In the former, if menstruation occurred during the voyage, the flow was apt, as a rule, to be excessive, but without any subsequent irregularity, while in the latter the subsequent irregularity was likely to be well marked, in one case menorrhagia for months afterward, while in another amenorrhœa, persisting for some months even, was not an unusual result, the cases of amenorrhœa being those in whom the menstruation was missed at its regular period during the voyage. These were generally young unmarried women. Such cases are quite commonly occurring in hospital practice among recently-arrived emigrants.

Dr. Sinclair inquired as to the effect of sea voyages upon Americans, going and coming.

Dr. Sinclair expressed his belief that in the case of the emigrants there was a strong element of nervous disturbance, due to leaving home. He had known such girls to go six months without menstruating. It was not exactly home-sickness, although there was a trace of this in the mental condition. The cause, he believed, was often to be sought beyond the sea voyage.

A MOTHER THIRTEEN YEARS OF AGE.

Dr. Cushing reported the case of a girl thirteen years and seven months old who had never menstruated but once, and had only once had connection, as she declared, who gave birth at term to a healthy child weighing seven pounds. She had an easy labor and a good getting up.

PODALIC VERSION, AND ABDOMINAL PRESSURE UPON THE AFTER-COMING HEAD.

Dr. Green reported a case which was of interest as illustrating, first, the advantage of version over the high-forceps operation in certain cases, and, second, the value of abdominal pressure as an aid in the delivery of the after-coming head. A multipara had been in labor some fifteen hours; the os was dilated, the membranes unruptured. The pelvis was found to be slightly flattened; the head had not engaged, but had extended and presented the brow; occiput left anterior; the child was large; fœtal heart not heard. The membranes were then ruptured, the head flexed, and forceps applied. Two efforts to extract were then made, when it was found that the head had again extended. Podalic version was then determined upon, and performed without difficulty; extraction was easily effected until the head reached the superior strait, from which the usual methods did not succeed in dislodging it. The student, whose case it was, was then directed to apply both hands over the fundus and to exert strong, evenly distributed pressure downward; thus aided by the powerful *vis a tergo* Dr. Green was enabled to accomplish extraction. The fœtus was partially asphyxiated, but was resuscitated after half an hour's effort; it weighed eleven and one quarter pounds. Both mother and child did well.

Dr. Blake said that his experience, which had been large, had been exactly opposite. In the case as reported by Dr. Green he would have spent an hour with the forceps trying to deliver the child in order to save it. In version is the risk, especially in the delivery of the head, where the pressure upon the neck or the head is often extreme. He had had, recently, a similar case, in which the head did not enter, and he concluded to try forceps, — Elliot's. The patient was placed first upon her back, then upon the side, when, after a tremendous amount of exertion, Dr. Blake succeeded in delivering a living child. Is there not danger to the uterine tissues, suggested Dr. Blake, from the pressure made externally? In one such case the woman died, and there was some doubt whether external pressure and consequent injury to the wall of the uterus might not have contributed to the fatal result. He would certainly never think of trying version until having given forceps a fair trial.

Dr. Green said he intended to restrict the question to pressure upon the after-coming head, the body being born, when two hands will clasp the head with a uniform, even pressure.

Dr. Richardson said he would side with Dr. Green in this question. Formerly having favored forceps against version in such cases, during the past four or five years his opinion had been gradually but surely undergoing a change, so that now he would rarely try forceps in a narrowed brim; he would do version in place of the high application of the forceps. His reason was that version is easy till the head is reached, and this is manageable if controlled during the process. Dr. Richardson reported a case to which he was called to do craniotomy, and version was performed in ten minutes, aided by steady, uniform pressure upon the head, so directed as not to compress the uterus. The child's life was thus saved. In the lying-in hospital he had not done high forceps for four or five years, and did not remember a still-birth from version during that time.

Dr. Green said that one great advantage of version over long forceps lay in the fact that the after-coming head entered the pelvis by a smaller diameter than the first-coming head, owing to its wedge-shaped conformation. He believed that a careful, tenative use of the forceps was permissible in slightly flattened pelves, but thought that version was a safer operation for both the mother and child when one or two well-directed efforts with forceps had been unsuccessful.

Dr. Richardson remarked that there was a scientific objection to the use of forceps high up, inasmuch as the difficulty lies antero-posteriorly, while the application of the blades is lateral, and these cannot exert so much power nor to the best advantage in that position.

Medical and Surgical Journal.

THURSDAY, MAY 8, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

THE CÆSAREAN SECTION AS PERFORMED BY SAVAGES.

THE tendency of late years to study the natural history of disease has extended itself to the phenomena of labor, and an attempt has been made to gather hints for rational obstetric practice from cases where nature has her most perfect work. Numerous descriptions have been published by various observers. Especially much of ethnological as well as medical interest is embodied in the recent compilations of Dr. Engelmann, of St. Louis. The latest contributor in this field is Mr. R. W. Felkin, who read a paper on Labor in Central Africa before the Obstetrical Society of Edinburgh, in January, which is published in the *Edinburgh Medical Journal* for April.

The usages in the various tribes differ widely. In one the woman sits on a fur spread over deep sand, which "supports" at once her perinæum and her back. In several a semi-erect position is taken, with the feet raised on a sort of stirrup, while attendant men or women compress the abdomen more or less energetically by swathes or by direct pressure. Sometimes the woman kneads her abdomen over the blunt end of a post fixed in the earth. In some tribes when the labor is delayed the patient sits over a pot with boiling herbs, which in turn is over a fire in the earth. The rising vapor is supposed to soften the unyielding passages, and conduce to an easy labor. In other tribes the women support themselves from a high horizontal bar by the hands, and bring forth their child while in a standing posture. In short, all sorts of positions are adopted, many of which are similar to those which have been made familiar to us by descriptions from other sources. It is interesting to note that this writer does not find that labor is, as a rule, the easy and painless matter among these women that some have supposed.

In a few of the tribes the writer found abdominal section to be practiced. Indeed, it seemed the only obstetrical operation that was known. In one village preparation had been made to perform this operation on a young woman who had been two days in labor, but whose only trouble was uterine inertia. Mr. Felkin, with much difficulty, prevailed upon the friends to allow him to put on the forceps, and delivered the woman without difficulty, to their great astonishment. In Uganda alone among the countries of Central Africa abdominal section is practiced with the hope of saving both mother and child. The author gives a description of this operation as he saw it performed there, and one cannot but be struck with the remarkably intelligent and successful manner in which it was done, considering the intellectual status and surroundings of the operator. Any comparison between the advantages enjoyed by a "surgeon" like this savage of Uganda and those renowned Arabian physicians, for instance, of the early centuries of our era, whose works have come down to us, is out of the question; yet we do not recall any professional achievement ascribed to Avicenna or Averroes which was more creditable than this operation of the savage of Central Africa. Believing it will be of interest to our readers, we make room for Mr. Felkin's description: —

"The patient was a fine, healthy-looking young woman of about twenty years of age. This was her first pregnancy. I was not permitted to examine her, and only entered the hut just as the operation was about to begin. The woman lay upon an inclined bed, the head of which was placed against the side of the hut. She was liberally supplied with banana wine, and was in a state of semi-intoxication. She was perfectly naked. A band of mbugu or bark cloth fastened her thorax to the bed, another band of cloth fastened down her thighs, and a man held her ankles. Another man, standing on her right side, steadied her abdomen. The operator stood, as I entered the hut, on her left side, holding his knife aloft with his right hand, and muttering an incantation. This being done he washed his hands and the patient's abdomen, first with banana wine and then with water. Then, having uttered a shrill cry, which was taken up by a small crowd assembled outside the hut, he proceeded to make a rapid cut in the middle line, commencing a little above the pubes, and ending just below the umbilicus. The whole abdominal wall and part of the uterine wall were severed by this incision, and the liquor amnii escaped. A few bleeding points in the abdominal wall were touched with a red-hot iron by an assistant. The operator next rapidly finished the incision in the uterine wall; his assistant held the abdominal walls apart with both hands, and as soon as the uterine wall was divided he hooked it up also with two fingers. The child was next rapidly removed, and given to another assistant after the cord had been cut, and then the operator, dropping his knife, seized the contracting uterus with both hands, and gave it a squeeze or two. He next put his right hand into the uterine cavity through the incision, and with two or three fingers dilated the cervix uteri from within outwards. He then cleared the uterus of clots and the placenta, which had by this time become detached, removing it through the abdominal wound. His assistant endeavored, but not very successfully, to prevent the escape of the intestines through the wound. The red-hot iron was next used to check some further hæmorrhage from the abdominal wound, but I noticed that it was very sparingly applied. All this time the chief 'surgeon' was keeping up firm pressure on the uterus, which he continued to do till it was firmly contracted. No sutures were put into the uterine wall. The assistant who had held the abdominal walls

now slipped his hands to each extremity of the wound and a porous grass mat was placed over the wound and secured there. The bands which fastened the woman down were cut, and she was gently turned to the edge of the bed, and then over into the arms of assistants, so that the fluid in the abdominal cavity could drain away onto the floor. She was then replaced in her former position, and the mat having been removed, the edges of the wound, that is, the peritonæum, were brought into close apposition, seven thin iron spikes, well polished, like acupressure needles, being used for the purpose, and fastened by string made from bark cloth. A paste prepared by chewing two different roots and spitting the pulp into a bowl was then thickly plastered over the wound, a banana leaf warmed over the fire being placed on the top of that, and, finally, a firm bandage of mbugu cloth completed the operation.

"Until the pins were placed in position the patient had uttered no cry, and an hour after the operation she appeared to be quite comfortable. Her temperature, as far as I know, never rose above 99.6° F. except on the second night after the operation, when it was 101° F., her pulse being 108.

"The child was placed to the breast two hours after the operation, but for ten days the woman had a very scanty supply of milk, and the child was mostly suckled by a friend. The wound was dressed on the third morning, and one pin was then removed. Three more were removed on the fifth day, and the rest on the sixth. At each dressing fresh pulp was applied, and a little pus which had formed was removed by a sponge formed of pulp. A firm bandage was applied after each dressing. Eleven days after the operation the wound was entirely healed, and the woman seemed quite comfortable. The uteriue discharge was healthy. This was all I saw of the case, as I left on the eleventh day. The child had a slight wound on the right shoulder; this was dressed with pulp, and healed in four days."

ETHERIZATION BY THE RECTUM.

The administration of ether by the rectum has attracted much attention in Boston as well as in other places during the past fortnight. The advantages of such a mode of administration in certain cases would evidently be very great. It would render it possible to maintain perfect anæsthesia during operations about the head and face without incommoding the operator by the presence of the etherizing apparatus in the field of operation. Such a condition might well be purchased at the cost of some other inconvenience. Some of the operations about the face are rendered peculiarly trying by the struggles of patients just sufficiently out of ether to blindly struggle, and the length of such operations is sometimes greatly prolonged by the necessity of stopping frequently to renew the anæsthesia. The new method promised freedom from these difficulties. It promised at first still more, for it seemed to present certain advantages. It diminished in certain cases the stage of excitement and reduced to a minimum the tendency to vomiting and did away with the uncomfortable local effects that sometimes followed the contact of the vapor with the throat and air passages. Such at least was the inducement to try the new method held out by the report of Dr. Mollière, of Lyons, which first drew attention to the subject in this country, and the earlier cases, in Boston at least, confirmed the impression; but subsequent experience has shown that if there are advantages there are also grave objections to the method. In many cases the effect has been out of proportion to the amount used, the ether continuing to be absorbed after anæsthesia was already complete until it became profound, sufficient in certain cases to cause anxiety. In these cases in which the insensibility grows deeper and deeper, it is impossible to withdraw the anæsthetic. A rectal tube fails to evacuate any sufficient quantity of gas, and one can only have recourse to stimulants and general measures until the effects have passed away. This prolonged effect has followed the smaller doses and in patients where there was no reason to expect such results. These cases have not rallied easily. In doing away with the local difficulties about the air passages other local difficulties have shown themselves in the rectum and bowels. The diarrhœa has in some cases been marked, and occasionally blood has been passed in sufficient quantities to prove serious, while the vomiting has also been in these same cases quite as severe as in patients anæsthetized in the usual manner. In addition, certain cases have proved quite intractable to the new mode of administration within any reasonable time, and inhalation has been added. A very few inspirations in addition to the amount absorbed by the bowels have proved sufficient.

In general the amount of ether necessary has been small; about two ounces has ordinarily proved sufficient to induce insensibility, though much larger quantities have been administered, and unpleasant symptoms have followed even from that small amount. From New York comes the account of a case, in which two ounces were administered to a child of eight months, in which bloody discharges and death occurred during the following night.

It is unnecessary to pursue the subject farther to show that these grave objections to the method will preclude its general use. Possibly it may be retained as an occasional adjuvant to the ordinary method, but it is not likely to come into general use as the ordinary method of inducing anæsthesia.

The present experience has been sufficient to formulate the following rules, which should guide any one desirous of using the new method, until further experience modifies them: —

Rectal etherization should be reserved for cases in which there is some special objection to the administration by inhalation.

It should be made use of only with robust adults.

In general two ounces should be regarded as a sufficient dose: that dose should be exceeded only with great caution.

When insensibility is fairly established the administration should be stopped.

THE NEW YORK STATE ASYLUM FOR INSANE CRIMINALS.

THE twenty-fourth annual report of the superintendent of the State Asylum for Insane Criminals at Auburn shows that during the last fiscal year 178 patients were treated, of whom 168 were males, and ten females; that two died, and that twenty-nine were discharged. Of the latter number fifteen men and one woman had recovered. The percentage of deaths was 1.13 of the whole number treated, and 1.36 of the average daily population, this being the fifth time in the history of the asylum that the death-rate has fallen below one and one half per cent. of the average daily number under treatment. The report states that during the year no form of mechanical restraint has been used, nor has the necessity of seclusion, as a means of restraint, been of frequent occurrence, the daily average of seclusion for the year being but a little over one half of one per cent. The daily average number of patients to whom medicine was administered for the purpose of inducing sleep was less than one tenth of one per cent. (.093).

In January, 1883, the manufacture of shoes and slippers for the men was commenced, and has been in successful operation ever since among some of the patients. An effort has also been made to provide further occupation to such of the patients as are desirous and able to work, and who are likely to be benefited thereby, by sending them out on farms in the vicinity of the asylum to work on shares. Care is exercised in the selection of patients in order that only those who can be relied on to conduct themselves properly may be allowed to go, each party sent out being in the charge of one or more responsible attendants who usually work with them. In speaking of this the superintendent, Dr. Carlos F. MacDonald, says: "While no money consideration has been asked or received for the labor of patients the asylum has undoubtedly been pecuniarily benefited by the proceeds thereof in the matter of supplies obtained, but this should be regarded as of very secondary importance in comparison with the marked benefit, mentally and physically, which the patients themselves have obtained from being thus pleasantly and usefully occupied. In fact, a noticeable improvement has been observed in the condition of every patient sent out to work, while in two instances complete restoration of mind resulted where recovery was not expected. Applications for permission to go, on the part of patients, were so numerous that some had to be denied, and all who obtained the privilege evinced their appreciation thereof by uniform good conduct and satisfactory work. The effort to provide occupation for the patients in the manner described was experimental, and had to be carried out under embarrassments and anxieties that would not be encountered if the asylum were located on, or had under its control, a farm whereby its inmates could obtain healthful and necessary occupation, and the institution the full benefit of their labor, without exposing them to the gaze of morbid curiosity or subjecting the asylum to the charge of competing with outside labor. The satisfactory results of the experiment would seem to demonstrate beyond question the necessity of providing the institution with a farm for the benefit of its inmates."

MEDICAL NOTES.

— Drs. H. J. Bigelow and R. M. Hodges have resigned their position as surgeons at the Massachusetts General Hospital.

— On the 21st of April numerous petitions were sent to the United States Senate calling for the passage of a bill "Requiring the Employment of Different Schools of Medicine in the Government Service." The returns made to the Michigan State Board of Health of medical practitioners in that State represent some seventy-five different "schools" of medicine, among them the "Indian," the "Cureopathic," etc. If Michigan can furnish seventy-five schools, when the other States are heard from there will probably be enough schools to "go around" for all the places.

— The native officials in Egypt are found by the representatives of the English government to be rather lax in the performance of their duties. Recently one of the native governors neglected to report to the authorities some cases of cattle plague which he had been instructed to look out for, and which had occurred in his district. He was immediately removed from his office to serve as a warning to the others. The warning succeeded beyond expectation. The other governors all forthwith sent statements of extensive epidemics in their districts, which naturally alarmed the authorities. On investigation it was found that these cases were purely figments of the imagination. The governors had learned that what had cost the delinquent his place was lack of reports of cattle plague, so they were resolved to be on the safe side.

— We find the suggestion in a contemporary, of holding the hands over strong aqua ammonia for a moment as a ready means of ascertaining the existence and location of small abrasions needing a touch of the caustic before holding a post-mortem examination; the smarting will quickly reveal all the sensitive or abraded places, however minute.

— At a recent meeting of the Medical Society of Columbia the president laid before the Society an examination of urine which a man, calling himself Dr. W. H. Hale, had made for a very intelligent patient. It is vouched for as an actual copy: "Analysis of Urine. — Specific gravity 120; excessive alaline; hippuric acid, 7 to 10 per cent.; traces of nerve-casts; acid reaction; temperature 93°. — W. H. HALE."

— We are requested to warn the medical fraternity against a very plausible impostor representing himself as a physician from South Carolina accidentally in want.

NEW YORK.

— At the last meeting of the County Medical Society, held Monday evening, April 28th, Dr. Joseph A. Andrews read a paper on Trachoma, and the Æti-

ology of Jequirity Ophthalmia, in which he stated that after a series of very careful experiments he came to the conclusion that Sattler's claim, that the disease was due to a special micrococcus, could not at present be substantiated; although it was possible that it might depend on such a micro-organism. At all events it seemed probable that the affection was really promoted by micrococci of some kind. The essential cause of jequirity ophthalmia was probably a ferment developed after the application of the agent to the eye. Dr. Knapp coincided in the opinion that the latter was produced by a chemical poison rather than a bacillus, and the discussion of the paper, which was brought to a close by Dr. Andrews, was also participated in by Drs. Pooley, Gruening, and Brandeis. On motion of Dr. A. Jacobi the approval of the Society was recorded of a bill entitled An Act to Provide Additional Accommodations for the Common Schools in the City of New York, the passage of which had been recommended by the Board of Education, and which provides that bonds to the extent of $2,000,000 should be issued by the city for the purpose named.

— At the last meeting of the Board of Health Sanitary Superintendent Day presented a report embodying the results of an investigation in regard to the adulteration of coffee by poisonous coloring matter. From this it appeared that for years green Gautemala and Maracaibo coffee had been taken to certain mills in Brooklyn and treated in this manner to make them resemble Government Java. The analysis of the coloring matter showed that it contained considerable quantities of arsenic and lead, and among its ingredients were chromate of lead, ferro-cyanide of potassium, yellow ochre (which frequently contains arsenic), umber, Venetian red, lamp-black, gum Arabic, soap-stone, and charcoal. It was estimated that every cup of coffee made from "Java" coffee prepared in this way contains one sixtieth of a grain of arsenious acid. It was further discovered that Rio coffee, which is apt to have a dull-gray color in the bean, was frequently placed in a large revolving cylinder and treated with a mixture of chrome yellow and Prussian blue, by which it is colored a handsome green. The Board at once took action in regard to the suppression of these criminal and dangerous practices.

— Dr. Elwyn Waller, chemist to the Health Department, has submitted to the Board a report of the analyses made by him of five samples of ordinary vinegar pickles obtained from different dealers. In all the samples analyzed it was found that an injurious proportion of copper, ranging from nine to two parts in one hundred thousand, had been used for coloring purposes.

— On the afternoon and evening of April 29th a kirmess, or Dutch fair, was held at the Metropolitan Opera House in aid of the New York Skin and Cancer Hospital. Having many attractive features it was a great popular success, and, no doubt, netted a large sum for the institution named. This hospital has secured a tract of land covering nearly one hundred and fifty acres, just beyond the city line, and it is expected that by midsummer cottage pavilions will be erected sufficient to receive any patient with cancer who may require assistance, whether the case is recent and suitable for operation or chronic and hopeless. For this purpose a fund of $100,000, which will cover the entire cost of the land and the erection of accommodation for one hundred patients, and a considerable portion of which has already been subscribed, is now being raised. The present city building in East Thirty-Fourth Street will still be continued as a reception hospital and for out-door clinics. The proceeds of the kirmess go to the "charity fund," under the management of the Ladies' Auxiliary Board, by means of which the managers are placed in a position never to refuse admission to any suitable case on account of poverty. Mr. John Jacob Astor has recently given $200,000 towards the proposed institution for the treatment of cancer alone, which those connected with the New York Skin and Cancer Hospital have used every effort to have united with their own, but thus far without success.

— On the 29th of April it was reported that there had been sixteen deaths from scarlet fever in the village of Canandaigua within eight days, and that the local Board of Health had issued an order prohibiting public funerals, and recommending the adoption of other needful sanitary precautions.

— A male child is said to have lately been born at West Troy having three perfectly formed legs, the third protruding above the right hip. In the opinion of the medical men who have examined it the extra limb can be satisfactorily amputated when the child gets stronger.

Correspondence.

LETTER FROM WASHINGTON.

Messrs. Editors, — The medical profession in Washington have just finished the spring round of college commencements, hospital fairs, etc., in time to welcome with the first week of spring weather their friends among the visiting physicians, who are arriving here rapidly. The Medical Department of Georgetown University held its commencement on April 30th, granting diplomas to seven graduates. Like all others of its class the attendance was very large, with the usual accompaniments of music and flowers. The Washington Training School for Nurses, on May 2d, graduated four nurses, quiet, refined, and earnest-looking women. The exercises were held in a church building (All Souls) generously loaned for the occasion, and in the presence of a small but appreciative audience. Very few medical men outside of those actually interested in the school were present, but the addresses, which were from Prof. D. W. Prentiss, the president of the Board of Trustees, Dr. P. J. Murphy, the surgeon-in-charge of the Columbia Lying-in Hospital, and Dr. W. W. Godding, superintendent of the Government Hospital for the Insane, were all worthy of the occasion, and merit earnest consideration. There are two classes who can make such a school prominent, the profession first, and the women of the community. Here the first class have not had as yet the opportunity for appreciating a first-class nurse except in occa-

sional cases in private practice, for the simple reason that there are no hospitals of any size which create a demand for them. Providence Hospital is under the nursing of Sisters of Charity. The Columbia Hospital can accommodate but a few, and from its peculiar field of labor the profession generally sees but little of its workings. The Freedmen's Hospital also takes a few, but its wards are not utilized by the mass of the profession. What the new Garfield Hospital is going to do remains a problem. Its friends believe that it will grow in importance and usefulness, as there is a positive need for it, and will before long furnish a suitable field for professional growth. The women could do a great deal, but they are already overburdened with entertainments for the benefit of the Children's Hospital, which should have been mentioned with the others as a small but well-defined field for nurse-training, of the Garfield Hospital, church orphanages, etc., etc., which task their ingenuity and time very seriously. To be a success such enterprises must become fashionable; perhaps some day the Nurses Training School may attain to that proud distinction.

Writing of fashion, doctors' lunches have become quite the thing. We have had two here recently, one given by Dr. Toner to Dr. Warren Bey, and the other by Dr. Jos. Taber Johnson to Dr. Mundé, of New York, and very enjoyable affairs they were, only Johnson's punch was a little too strong to be taken in the middle of the day by any one who still had his rounds to make. A conversation on this subject was overheard as occurring between two ladies: "What are all these doctors' buggies doing here?" "It is a doctor's lunch, my dear." "A doctor's lunch! Well I never heard of doctors stopping to have a formal lunch before."

The American Surgical Association were certainly favored by Dame Nature during their meeting here this week. All the foliage was well out, and everything looks fresh and bright, and even the heat, with the exception of one day, Friday, was tempered to an agreeable degree. The city is looking its best now, and may give to some others of our medical neighbors the desire to reside permanently among us, when they retire from active practice, of course, and follow in the footsteps of Dr. Hammond, who is said to be about to build a marvel of a house on the Mexican plan, with a large central court roofed in with glass, etc. The late Dr. Marion Sims we know also intended to take up his residence here.

The meetings of the American Surgical Association were held in a large room in the National Museum, and surrounded by the park of the Smithsonian Institution. The room was so arranged that by a series of large screens the small body of men — for the attendance was not large — could be shut off quite satisfactorily from the empty space around, and the screens served the purpose of sounding boards, not as well as could be wished however; and as work is still going on in different parts of the open building an occasional sound would reverberate through into the room, annoying Dr. Flint, of the navy, who was exerting himself to relieve the meeting of all such disturbances. An occasional group of visitors would lounge in from the main hall, take a look at the Indian pictures which hung on the walls, and after listening for a few moments pass out, evidently thinking that the other curiosities were of more interest. Dr. Basil Norris, of the army, who was chairman of the Committee of Arrangements, seemed to be always on hand and rendering himself particularly useful and agreeable.

Very few of the Washington medical profession seemed to be present, and a number of faces were missed from the assemblage, such as Professor Gross and his son, Dr. J. C. Warren of your city, and others; but the general impression given, which was heightened by the manner and appearance of the President, Dr. Moore, of Rochester, N. Y., was that of a quiet, dignified, and earnest body of men, and the papers read and discussions held upon them partook of the same character; but as they will be fully reported in your columns elsewhere it is not necessary to particularize them here. Among those present, however, we must mention J. S. Billings, M. D., LL. D. (Edinburgh), U. S. A., whose latest honors do not seem to embarrass him. Think of a man leaving this country on April 2d, going to Edinburgh and participating with honor in the tercentary of her University, and being back at his post on April 30th, in twenty-eight days.

Professor Gross's paper, which was on Wounds of the Intestines, was read in his absence, and a telegram sent by the Association expressing to him their pleasure and profit in listening to his paper and their sympathy and hope for his speedy recovery. There were some forty members registered by the close of the meeting on May 3d, and a resolution was passed to dispense with the annual dinner, but notwithstanding that fact, twenty of the members dined together formally at one of the hotels. Quiet receptions were held on several evenings at the houses of physicians, and upon invitation from Professor Baird the Washington fish-hatchery establishments were visited.

In the election of officers the following were selected: President, Dr. William T. Briggs, Nashville, Tenn.; Vice-Presidents, Dr. J. C. Hutchinson, Brooklyn, N. Y., Dr. E. H. Gregory, St. Louis, Mo.; Secretary, Dr. J. R. Weist, Richmond, Va.; Treasurer, Dr. John H. Brinton, Philadelphia, Penn.; Recorder, Dr. J. J. Ewing Mears, Philadelphia, Penn.; Council, Drs. Henry F. Campbell, Augusta, Ga., Hunter McGuire, Richmond, Va., P. S. Conner, Cincinnati, Ohio, and Dr. J. S. Billings, D. C.

The Association will meet in Washington again in April, 1885, and Dr. Billings was elected chairman of the Committee of Arrangements.

In regard to the Code question, it may perhaps interest you to know that while nothing was said in the meetings with regard to it further than the reading of the report of the Secretary on the first day, to the effect that several resignations had taken place in consequence of the strict adherence of the Association to the Code, and these resignations appeared to be forced, the general tenor of conversation among the members was that the Code of the American Medical Association was to be taken as a matter of course.

Miscellany.

A BILL TO PREVENT THE SPREAD OF CONTAGIOUS DISEASES AMONG CATTLE.

A BILL to prevent the spread of pleuro-pneumonia and other contagious diseases among cattle has finally passed both houses of Congress, under the stimulating supervision of a committee appointed by a convention

of cattle raisers held in Chicago last November. The bill seeks to provide an interstate quarantine system, to establish a system of inspection under the control of the Commissioner of Agriculture, and appropriates a sum to indemnify owners of diseased cattle which may be slaughtered.

REPORTED MORTALITY FOR THE WEEK ENDING APRIL 26, 1884.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 2273 (no reports from St. Louis, New Orleans, Buffalo, District of Columbia, Milwaukee, and Providence): under five years of age, 1632; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 331, consumption 345, lung diseases 316, diphtheria and croup 88, scarlet fever 69, diarrhœal diseases 38, measles 32, typhoid fever 32, cerebro-spinal meningitis 16, erysipelas 16, malarial fevers 14, whooping-cough 12, puerperal fever nine, small-pox four, typhus fever one. From *measles*, Chicago eleven, New York nine, Baltimore seven, Brooklyn three, Philadelphia and Cincinnati one each. From *typhoid fever*, Philadelphia fourteen, Chicago seven, Pittsburg three, New York two, Nashville, Charleston, Lowell, Worcester, New Bedford, and Andover one each. From *cerebro-spinal meningitis*, Baltimore four, New York three, Chicago and Brockton two each, Cincinnati, Fall River, Lawrence, New Bedford, and Quincy one each. From *erysipelas*, New York five, Philadelphia, three, Boston and Newton two each, Brooklyn, Chicago, Baltimore, and New Bedford one each. From *malarial fevers*, New York and Brooklyn three each, Chicago two, Baltimore, New Haven, Nashville, Fall River, Chicopee, and Spencer one each. From *whooping-cough*, New York four, Baltimore three, Cincinnati two, Philadelphia, Brooklyn, and Chicago one each. From *puerperal fever*, Brooklyn three, Chicago two, New York, Philadelphia, Boston, and New Haven one each. From *small-pox*, Philadelphia, Chicago, Cincinnati, and Pittsburg one each. From *typhus fever*, Cincinnati one.

One case of small-pox was reported in Boston, Cincinnati one; scarlet fever 65, diphtheria 20, typhoid fever four, and measles four in Boston.

In 103 cities and towns of Massachusetts, with an estimated population of 1,404,364 (estimated population of the State 1,955,104), the total death-rate for the week was 15.63 against 16.60 and 16.00 for the previous two weeks.

In the 28 great towns of England and Wales, with an estimated population of 8,762,354, for the week ending April 12th, the death-rate was 20.4. Deaths reported 3418: acute diseases of the respiratory organs (London) 283, whooping-cough 192, measles 142, scarlet fever 63, fever 49, diphtheria 28, diarrhœa 25, small-pox (London eight, Liverpool four, Newcastle three, Birmingham, Sheffield, and Sunderland two each, Derby and Hull one each) 23. The death-rates ranged from 14.9 in Leicester to 31.3 in Wolverhampton; Sheffield 16.1; London 19.1; Leeds 20.1; Birmingham 20.2; Derby 20.3; Birkenhead 21.2; Nottingham 21.9; Blackburn 22.2; Newcastle-on-Tyne 22.4; Liverpool 22.6; Sunderland 22.9; Manchester 25.6. In Edinburgh 22.4; Glasgow 28.7; Dublin 23.0.

For the week ending April 12th, in the Swiss towns, there were 56 deaths from consumption, typhoid fever 27, lung diseases 25, diarrhœal diseases 14, whooping-cough five, diphtheria and croup four, scarlet fever two, small-pox, measles, and erysipelas each one. The death-rates were, at Geneva 31.6; Zurich 23.6; Basle 19.4; Berne 33.3.

The meteorological record for the week ending April 26th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps:—

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING MAY 3, 1884.

HARVEY, H. P., passed assistant surgeon, detached from Naval Hospital, Chelsea, and ordered to St. Mary's.

MCCARTHY, R. H., passed assistant surgeon, ordered to Naval Hospital, Chelsea.

WAGGENER, J. R., passed assistant surgeon, detached from St. Mary's, and ordered to the Hartford.

WISE, J. C., surgeon, detached from the New Hampshire, and ordered as member of Board of Examiners at Annapolis.

CRAIG, T. C., assistant surgeon, promoted to passed assistant surgeon.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM APRIL 26, 1884, TO MAY 2, 1884.

SHUFELDT, ROBERT W., captain and assistant surgeon. Relieved from temporary duty in Surgeon-General's Office, and ordered to report to Lieutenant-Colonel Basil Norris, surgeon United States Army, attending surgeon Washington, D. C., for temporary duty in his office. Paragraph 6, S. O. 100, A. G. O., April 30, 1884.

BARROWS, C. C., first lieutenant and assistant surgeon. Relieved from duty at Fort Grant, A. T., and ordered to report for duty at Whipple Barracks, A. T., relieving First Lieutenant W. E. Hopkins, assistant surgeon, who, upon being relieved, will report for duty as post surgeon at Fort Grant, A. T. Paragraph 1, S. O. 31, headquarters Department of Arizona, April 21, 1884.

PHILLIPS, JOHN L., first lieutenant and assistant surgeon (Fort Warren, Mass). Ordered to report for temporary duty to the commanding officer at Fort Preble, Me. Paragraph 1, S. O. 81, headquarters Department of the East, April 28, 1884.

CUYLER, JOHN M., colonel and surgeon, retired. Died at Morristown, N. J., April 26, 1884.

Changes in Stations of Medical Officers.
(Paragraph 2, S. O. 101, A. G. O., May 1, 1884.)

HEGER, ANTHONY, major and surgeon. From Department of Texas to Department of the East.

HAPPERSETT, J. C. G., major and surgeon. From Department of Texas to Department of the East.

BENTLEY, EDWIN, major and surgeon. From Department of the East to Department of Texas.

MIDDLETON, PASSMORE, captain and assistant surgeon. From Department of Texas to Department of Missouri.

KOERPER, E. A., captain and assistant surgeon. From Department of the East to Department of Dakota.

DICKSON, J. M., captain and assistant surgeon. From Department of the East to Department of California.

GIRARD, A. C., captain and assistant surgeon. From Department of Dakota to Department of Missouri.

GIRARD, J. B., captain and assistant surgeon. From Department of Arizona to Department of the East.

HALL, J. D., captain and assistant surgeon. From Department of Dakota to Department of the Columbia.

HALL, WM. R., captain and assistant surgeon. From Department of Missouri to Department of Texas.

CUNINGHAM, T. A., captain and assistant surgeon. From Department of the East to Department of Missouri.

MCCREERY, GEO., first lieutenant and assistant surgeon. From Department of Arizona to Department of Dakota.

COCHRAN, J. J., first lieutenant and assistant surgeon. From Department of Missouri to Department of Arizona.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The *Section for Clinical Medicine, Pathology, and Hygiene* will meet at 19 Boylston Place, on Wednesday, May 14th, at 7.45 o'clock. Dr. E. G. West will report a case of Myxœdema with Autopsy. Drs. F. Minot, R. T. Edes, Streeter, R. H. Fitz, F. G. Webber, J. J. Putnam, W. H. Whitney, and E. G. Cutler will take part in the discussion. Dr. W. N. Bullard will present an account of A Typhoid Epidemic. Dr. Morton Prince will open the discussion.

ALBERT N. BLODGETT, M. D., *Secretary.*

NORFOLK DISTRICT MEDICAL SOCIETY. — The annual meeting will be held at Rockland Hall, No. 2343 Washington Street, Roxbury District, Boston, on Tuesday, May 13, 1884, at two P. M. The Board of Censors will meet at one o'clock. Order of business: Report of Committees, Report of the Treasurer, Election of Officers, Incidental Business. Communications: —

A Case of Criminal Abortion with Retention of a Portion of the Secundines. E. F. Dunbar, M. D.

The Treatment of Fractures of the Femur without Splints. D. B. Van Slyck, M. D.

G. D. TOWNSHEND, M. D. *Secretary.*

EXCISION OF A PORTION OF INTESTINE, INCLUDING PART OF THE ILEO-CÆCAL VALVE, FOR THE CURE OF FÆCAL FISTULA IN RIGHT GROIN.[1]

BY C. B. PORTER, M. D.,

Surgeon Massachusetts General Hospital.

DURING the past five years great improvements have been made in the methods of operating on the intestinal tract, and to-day it is one of the most interesting and progressive of all the departments of abdominal surgery. Up to the year 1877–1878 an occasional bold operator had ventured to perform certain operations on the intestinal tract, such as suture of wounded intestine, or even resection of portions of gangrenous intestine found in the hernial sac, but, as a rule, the surgeon was content when dealing with strangulated hernia to leave the gangrenous bowel to slough off, or, at most, to remove it, and, in either case, to hope to obtain an artificial anus that could be treated later by various plastic operations and occasionally cured. In diseases of the intestine, such as stricture, malignant or otherwise, the only recognized operation was the formation of an artificial anus at some point. This operation was generally performed in the left loin for the relief of strictures of the rectum or the sigmoid flexure. The treatment of wounds of the intestine was almost always expectant, and, unless the intestine was lying outside the abdomen with its cut edges exposed, no treatment except rest and opium was adopted. Cases of suture with or without excision are, however, to be found recorded previous to the period mentioned. In 1727 Ramdohr excised about two feet of gangrenous intestine found in an inguinal hernia. One end was invaginated in the other and secured by sutures, and the patient recovered. Up to the year 1873 there had been recorded eighteen cases of resection of a portion of the intestinal tract, followed by circular suture. The operation is indicated (1) In cases of gangrenous hernia; (2) for the cure of artificial anus; (3) for new growths or stricture of the intestine; (4) for certain cases where tumors of other abdominal organs are so closely united to the intestines that they cannot be separated; (5) for internal strangulation and invagination with gangrene; (6) For lacerations and wounds of intestines. The first two indications are most frequently met, and it is in these cases that the operation has been most often performed.

In the tables of Madelung[2] and Bouilly[3] are collected fifty-four resections for gangrenous herniæ, followed by circular suture, with twenty-eight deaths, giving a mortality of a little over fifty per cent.

Operations for the cure of artificial anus are next in frequency. Of these I find twenty-five cases with nine deaths, a mortality of thirty-six per cent. The first of these operations was performed by Dr. R. A. Kinloch, of South Carolina, in 1863, for artificial anus following gunshot wound of the intestine. The patient recovered after the formation of a fæcal fistula.

Madelung gives nine cases of resection for new growths, seven cases of prolapsed and wounded intestines from abdominal injuries, three cases of wounds during laparotomy, and three cases of internal strangulation. The greater part of these operations was performed by German surgeons, and it is to them that we are mostly indebted for our present knowledge of the subject. England and America have furnished a very small number of cases. In Bouilly's table is mentioned the successful case of Dr. W. Fuller, of New York.[4] To this we can add two cases reported by Dr. Ill, of New York,[5] one of which recovered.

Up to date there have been recorded so far as I can discover one hundred and four cases of resection of intestine, with forty-nine deaths, a mortality of forty-seven per cent. Of these one hundred and four cases there have been recorded four cases where resection followed by suture of the intestine has been performed in the United States, with three recoveries. Beside the hundred and odd cases reported above, there are others on record where the exact lesion is not stated, or where wounds of the intestine made for different objects, or caused by accident, have been united by suture. These are all interesting as bearing on this operation and its history, and show still farther the feasibility of intestinal suture. Perhaps the case to be read cannot strictly be classed with the tabulated cases as it was not a resection of the whole calibre of the bowel; so small a bridge, however, united the large and small intestine that the operation was practically the same.[6]

The method of operating has been thoroughly described in all the journals both at home and abroad, but a brief account of some of the important details in the operation is, perhaps, not out of place here. The two principal points to be observed are the prevention of the entrance of fæces into the abdominal cavity, and a very careful adjustment of the serous surfaces. The intestine should be drawn out of the abdomen and surrounded by warm, carbolized towels, and, in cases where laparotomy has been performed, some operators bring the edges of the abdominal incision together with one or two temporary sutures, leaving outside only the knuckle of intestine that is to be operated upon. Various methods have been employed to prevent the oozing of fæces from the cut intestine, some preferring digital compression above and below the wound, while others use different forms of clamps for the purpose.

Madelung and others advise excising a somewhat wedge-shaped piece of the intestine, the apex of the wedge pointing toward the mesentery. The united intestine forms therefore an obtuse angle, and the point of suture is thus wider than the rest of the intestine.

Many forms of suture have been employed, among them the most important are the invagination suture of Jobert, now seldom used, and the Lembert suture with its various modifications by Czerny and others.

It is always to be remembered that serous surfaces must be opposed. This is very perfectly done by the Lembert-Czerny stitch, which is applied as follows: A row of very fine stitches is taken near the cut edge of the intestine through the serous and muscular coats only, a very fine half curved needle being used. These stitches should be near enough together to completely

[6] It may be mentioned here that there has been one case of resection of the pylorus in the United States, that of Dr. C. M. Richter, of San Francisco. [Western Lancet, 1882, vol. xi., p. 289.] The patient died the day following the operation.

close the wound and allow no liquid contents of the bowel to pass through the interspaces. A second row of sutures is then placed outside the first, the needle passing as before only through the serous and muscular coat, including a wider portion of the intestinal wall but not reaching the first row of stitches. In this way the peritoneal surfaces are rolled in and thoroughly opposed. A slight ridge is, of course, made on the inside of the bowel, but if the incisions have been made as recommended above, the lumen is not materially narrowed.

Two forms of suture have been used, silk and catgut, and opinions differ as to which is better. Silk is not open to the objection that it may be too quickly absorbed, as is sometimes the case with fine catgut; while catgut is supposed to be less irritating, and to cause less ulceration than silk. Some operators use silk for one row, generally the inner, and catgut for the other. Whichever material is at hand can safely be used if thoroughly carbolized, and a good result can be expected for wounds of this sort when properly treated, as they heal more rapidly and with less irritation than almost any other.

When we consider the results thus far obtained in a class of cases always severe, may we not hope and expect to see the operation much more generally adopted in this country instead of being looked upon as an experimental operation performed only by reckless surgeons in foreign hospitals? The history of the operation shows it to have been most carefully worked out by a great series of experiments on animals and a cautious advance, step by step, until the operation now stands as one not only justifiable, but most advisable and proper in certain cases.

My patient, Mrs. B., aged sixty-seven, entered the Massachusetts General Hospital August 8, 1883. She had a right inguinal hernia at the age of eight years, and at some subsequent time, date unknown, had developed the same condition on the left side. Three years previous to her admission the hernia of the right side became strangulated. An operation for relief was performed, and according to her statement a portion of the intestine sloughed, and artificial anus was formed in the right groin. Twelve days previous to entrance the hernia of the left side became also strangulated. Herniotomy was performed, the intestine returned into abdominal cavity, and she entered for the care of the resulting wound on left side. In about two weeks this wound was healed, and the only remaining trouble was the almost constant discharge from the artificial anus on right side. September 12th patient was etherized, and an operation for closure of the fistula was performed by Dr. John Homans. The edges were refreshed and closed by silk sutures. Two days subsequent it was noticed that the dressings were soiled by fæcal matter. From that time to December 1st, about two months and a half, the condition varied, the opening would apparently close for a few days more or less, and then suddenly break out again with fæcal discharge. December 2d a small abscess formed two and a half inches nearer the median line, which also discharged fæces. December 10th she had a chill and high temperature, which ushered in an attack of erysipelas, from which she had recovered December 31st. Patient was extremely anxious to have another operation for cure, as she was in such a deplorable condition. Alone in the world, without friends, entirely dependent upon charity, the offensive condition in which she was would prevent her from obtaining any employment, and she would have no home but the almshouse. I talked with her a number of times, explaining fully the danger of any radical operation for cure, and she always insisted that it was her right to demand at my hands anything which afforded a chance of relief, stating that she preferred to die rather than live as she was.

According to her wishes I operated January 11, 1884, the bowels having been cleaned out by cathartic and enemata. The condition was this: two fæcal fistulæ in right groin, one about one and one half inches from spine of pubes, and the other about three inches farther outside; each about one inch above Poupart's ligament. A bougie was passed into one of the fistulous openings (the one highest up in the groin) emerging from the other opening three inches lower down. This was then cut down upon, the tissues consisting of hard cicatricial masses, and the entire cavity laid open. This cut divided the lower margin of the abdominal ring, and laid open the hernial sac; the incision was then prolonged downwards to expose the whole sac, making a wound through the skin of abdominal wall four inches long. Two openings into the intestine were found about one inch apart. These were connected by a cut made on the director dividing the superficial epigastric artery, which was first tied with a double ligature. The opening in the intestine was then seen to be in the ileum and cæcum, just at their union. The finger passed readily into the large intestine, but the attempt to introduce it into the small intestine through the ileo-cæcal valve was impossible as the cicatricial contraction involved the valve itself, and the opening was not larger than a small lead pencil. The dilator was introduced and this opening stretched, then with the forefinger of the left hand introduced into the opening a dissection was made to release the intestine from its cicatricial attachments to the abdominal wall, necessitating a section of the muscles from the external abdominal ring outwards for about four inches. This done, the intestine was free from all but its mesenteric attachments. To close up the wound in the intestine the expediency of cutting out a complete section of the intestine was considered, but was not thought wise, as it would involve removing the vermiform appendix and portions of cæcum and ileum. The cicatricial margin of the opening was trimmed off. The opening then involved about four fifths of the calibre of the bowel. The edges of this wound were then approximated, but as one side was small and the other large, intestine, the edges would not lie together smoothly. To obviate this difficulty a longitudinal cut was made in the small intestine, thus giving a longer edge of cut surface, and forming a sort of oval-shaped wound, which could be approximated accurately to the cut edge of the large intestine. The wound was then sewed up with silk sutures as follows: The needle was entered about one half inch from the wound, penetrating the peritoneal layer, then traversing the middle layer (muscular) of the gut, and emerging one eighth inch from the margin of the wound, having left the mucous layer untouched. The needle was then entered at the opposite side of the wound, in a corresponding manner traversing the middle layer, and emerging about one half inch from the wound. Ten sutures were introduced in this way. When these were drawn tight they rolled in the free margin of the wound, thus bringing two serous surfaces in contact, and turning the cut edge into the interior of the bowel.

The intestine was then allowed to fall back in the abdominal cavity after additional silk sutures had been placed between the previous ones, making twenty in all.

The ring and abdominal opening were then brought together and sewed with fine silver wire, the sutures passing through the peritonæum and fascia of the deeper muscles, but not the skin. The ends were cut short and the points bent over. Five sutures were thus placed. The skin was then united by silk sutures, a large-sized drainage tube, three inches long, being inserted into the abdominal cavity.

A graduated compress of carbolic gauze was then placed over the wound, and a full Lister dressing surrounding the abdomen and thigh, the whole being confined by a spica bandage, firmly sewed together. The whole operation was done under carbolic spray and all antiseptic precautions, occupying in all two hours and three quarters. There was but very little hæmorrhage, the vessels of the skin being tied before the abdomen was opened. There was no escape of fæcal matter at any time. The tract of the small sinus first opened was thoroughly curetted before any other cut was made.

The condition of the patient was excellent throughout, the pulse being full and moderate. About one and one half pints of ether were used.

The patient rallied well from the ether, and vomited but very little. In the evening she took hot, strong, black coffee, and brandy and soda water, but before this she had two enemata of brandy, ℥ss. each.

January 12th, the day following, patient was very much nauseated, and did not retain anything on her stomach. She then took enemata of beef tea and brandy every three hours, but after the third enema she failed to retain this. She was then ordered to have nothing at all. The night pulse was good, but after an attack of vomiting it became very weak and rapid for a few minutes. Temperature was 101° F. *Passed flatus freely.* During night she took, in all, brandy ℥ij., beef tea ℥vss., coffee ℥iiss. She had morphine, grain one eighth, subcutaneously, and during the night grain one sixth by suppository.

January 13th. She had almost constant retching, but otherwise her condition was good. She seemed rather unreasonable and complaining. She took, during the night, tea ℥ij., brandy ℥iij., coffee ℥i. morphine grain one sixth. Temperature is 100.3° F. Ordered

℞ Chloral . . . . . gr. xv.
Potass. bromid. . . . . gr. xx.

every four hours by enema. Also bicarbonate of soda and water by mouth.

January 14th. Condition excellent. Last night she took brandy ℥i., beef tea ℥ij. Enemata have been retained. During the day she has taken brandy ℥i., beef tea ℥iiiss., coffee ℥iij., tea ℥iii. No opiate. Temperature is normal. Pulse 95, full and strong. Has no tympanites or tenderness of abdomen. Has no pain, except an occasional sharp, darting pain in lower part of abdomen. She seems herself again mentally. To-day has had two dejections, the last being involuntary.

January 15th. Temperature up a little (100° F.). No leakage from dressing, but some slight odor. Lister changed under spray. Very little union of edges of wound. Drainage tube removed, and a smaller and shorter one inserted, not penetrating so deeply as to enter peritoneal cavity. Iodoform placed on wound, and full Lister dressing replaced. (She has taken to-day brandy ℥iss., beef tea ℥viii., milk ℥ivss. Enema of bromide and chloral given only once to-day, as patient was perfectly quiet and comfortable.)

January 16th. (Very comfortable. Has taken a large amount of nourishment to-day, namely, beef tea ℥xxi., coffee ℥xxiij., milk ℥v., brandy ℥v. Temperature below 100° F.)

January 17th. Says she feels as well as she ever did, except for weakness. (Has taken to-day brandy ℥i., beef tea ℥xxi., milk ℥xiij., coffee ℥x., tea ℥v. The brandy, although given in ℥ij. doses only, causes some flushing; reduced to ℥i. doses.)

January 18th. Slight staining of dressing; changed under spray. The wound of skin has gaped for its whole length, the edges being composed of hard cicatricial tissue, and the bottom of the wound being an old sinus. Short, small drainage tube inserted at middle of wound, and another small one at lower end in place of the original tube. She has taken to-day some stewed oysters and small sandwiches of raw scraped beef.

January 20th. Lister changed. Tube at lower end of incision shortened a little. There is some pocketing of pus at middle of wound.

January 22d. Lister. Small pocket above mentioned dilated.

January 24th. Temperature normal. Feels well. Normal dejection yesterday.

January 25th. Has been doing perfectly well until this noon, when she had a chill and rise of temperature. The dressing was changed, and the wound seen to be looking very well. The skin was a little tense, and there was a general marked induration all about. A phenyle poultice, consisting of cotton batting wrung out in hot phenyle and covered with oiled silk, was applied, and iodoform was sprinkled into the wound. Felt very restless and was querulous, quite different from her ordinary self.

January 26th. The phenyle poultice was changed every fifteen minutes until midnight, a dry gauze dressing being then applied. This morning upon removing the dressing pus was seen to escape by two openings in the wound; the tenseness and induration had disappeared to a great extent. On coughing about ℥ss. of fetid pus appeared at upper end of wound. Fomentations replaced and renewed every half hour until night.

January 29th. Had rise of temperature last night, probably due to extra exertion caused by sitting up in bed, or perhaps to bowels. Patient was given an enema with good results. Last night appeared weak in her mind, talking in a childish manner, but responding to questions rationally.

January 30th. Mental condition all right. Wound looking perfectly. Tube shortened to a small piece at lower end of sinus. Has had three loose dejections to-day.

February 2d. Temperature to-night 102.5° F., due, possibly, to the fact that she was somewhat excited by the visit of the students. Has had two dejections.

February 5th. Has been out of bed, allowed to stand on her feet, and take a step or two.

February 6th. Drainage tube omitted, and the wound, which is merely superficial, packed with charpie and myrrh. Almost no dischage from the wound. Patient is gradually gaining in strength, and her mental condition much less childish than a few days ago.

From this time on the patient has gradually im-

proved, the wound has entirely healed, and temperature and dejections have been normal. There has also been a constant increase in strength.

SPINAL IRRITATION AND NEURASTHENIA.[1]

BY G. LIEBMANN, M. D.

IT appears that the word "neurasthenia" is at present in everybody's mouth; that it is, in fact, like a big pot into which various nervous and mental disorders of depression are thrown pell mell, and without much discrimination.

Although Beard and Rockwell, in their work on medical and surgical electricity (1875), say that spinal irritation almost always forms a part of hysteria and neurasthenia, constituting, as it were, a subdivision or accompaniment of them, they still hold, it may be with a certain degree of reluctancy, that spinal irritation is a disease per se "when the spinal tenderness and the symptoms that directly flow from it overshadow other accompanying conditions." We see, therefore, that these authors only conditionally identify neurasthenia (nervous exhaustion) with spinal irritation, and I, for my part, cannot comprehend how Rosenthal, and, if I am not mistaken, Erb, come to the assertion that these, our American authors, proposed the term of neurasthenia for the so-called depressed form of spinal irritation. The fact is, Beard and Rockwell are the first who described the symptoms of nervous prostration, pure and simple, under the name of neurasthenia, but vindicated to spinal irritation its character of a separate and independent disorder. They relate cases in which the least physical or mental exertion was followed by extreme exhaustion *without spinal tenderness*, even one case of neurasthenia in a plethoric patient in whom not a trace of an organic lesion of the cord could be detected.

Each practitioner ought to do his own thinking, and although looking up to the great lights of our science with admiration, still have his eyes open, and see how far his own experience tallies with the teachings of authorities. If we do this with regard to the disease in question (neurasthenia) we plain practitioners find that uncomplicated neurasthenia is a very rare disease. In a practice of twenty-seven years I scarcely can recall more than five cases of idiopathic neurasthenia which came under my treatment if I exclude those cases of nervous prostration which depended upon anæmia, losses of blood, and protracted lactation. I say cases of *idiopathic neurasthenia*, for many cases of apparent nervous exhaustion are no distinct and separate disease *per se*, but reflexes caused by underlying organic diseases of the sexual organs. Notwithstanding the assertion of Rosenthal that the depressed form of spinal irritation is identical with neurasthenia, numerous cases in my practice teach me otherwise, and that the irritation in question is not a spinal neurosis, but a symptom of chronic prostatitis in the male or chronic ovaritis or metritis in the female. Apart from my own observations of cases of so-called spinal irritation (with depression) or neurasthenia in young men, Rosenthal, in enumerating the symptoms of spinal irritation, also lays great stress on the prostatic symptoms. The following are his words: "Other important disorders also appear on the part of the genital functions. In general the patients are easily excitable, but the erections and virile power are deficient; ejaculation of semen is often premature, and followed by distressing sensations in the back and legs. When the mind is occupied with erotic thoughts, and even after defecation or micturition, some drops of prostatic fluid (almost always without admixture with spermatozoids) frequently appear in the meatus. True spermatorrhœa only occurs at great intervals. Chronic pollutions, on the other hand, are frequent, and when they follow one another in rapid succession they greatly aggravate the manifestations of the disease. In the majority of patients the urethral canal presents, especially in the prostatic portion, an acute sensitiveness even when a sound of small calibre can be introduced without difficulty." Who reading this graphic description does not think at once of the so frequent chronic prostatitis with all its tortures to the patient and the attending physician as well? As all the chronic disorders of the pelvic organs through the sympathetic nervous system produce the most serious bodily and mental disturbances, and especially a hypochondriacal state of the mind, the disorders of the prostate gland and ovaries do so *par excellence*. But although these disorders, by means of disturbances of the vaso-motor nerves within the spinal column, may bring on *temporary* hyperæmia or anæmia, we have no right to isolate these symptoms from the existing original pelvic disorder, and to classify them under the head of "spinal irritation with depression," for I always find that in the course of these pelvic lesions the spinal symptoms are but evanescent, and coincident with the functioning or excitation of the respective diseased organ. Furthermore the nervous weakness is but apparent, as best shown by the results of treatment. Although these patients complain of bodily and mental fatigue (see also report of cases of urethral stricture by Drs. G. H. Tilden and F. S. Watson), a tonic treatment, often and faithfully employed by me, never accomplished anything. Again, the much-extolled *rest*, doing so much good in real neurasthenia and in true spinal irritation, gives bad results in the symptomatic form.

I come, therefore, to the conclusion that neurasthenia and spinal irritation are two *different* and *distinct* things, and that cases of the so-called depressed form of spinal irritation of Rosenthal neither belong to the one nor the other, *and are but symptoms of another existing disease of the pelvic organs*. For whilst in real spinal irritation by means of a false innervation and consecutive vaso-motor disturbances these pelvic organs may be affected secondarily, or, on the other hand, might have ceased to be diseased some time before the advent of the spinal symptoms, in pseudo-irritation the pelvic lesions always precede the symptoms of irritation, and these in return disappear with the disappearance, or at least abatement, of the organic pelvic disturbances.

When young men with all the symptoms of a chronic prostatitis, and complaining of some lumbar pain and hebetude, and exhibiting more or less vetebral tenderness, call on their physician, or young married ladies with some slight trouble of the pelvic organs apply to our skill and sympathy, and are frightened out of their wits by being told why they suffer from spinal irritation, I unhesitatingly say *this is downright cruelty*, for the impression thus made on the patient is demoraliz-

[1] Read at a meeting of the Section for Clinical Medicine, Pathology, and Hygiene of the Suffolk District Medical Society, March 12, 1884.

ing and discouraging in the extreme, and besides we say what is not true. I therefore propose the following classification of the disorders: —

(1.) Neurasthenia.
(2.) Spinal irritation.
(3.) Pelvic rachialgia.

I. NEURASTHENIA.

This is, as the term itself implies, a nervous weakness, uncomplicated with organic disease, a diminution of nerve force, depending upon a hitherto unknown disturbed condition of the nerve centres. As we do not know, so far, the material basis of this condition, we have to consider the malady as a functional exhaustion of the motor and intellectual sphere. The least bodily or mental exertion causes fatigue and rapid exhaustion, and any mental labor brings on nervous excitement and inability to go on in the work. As a rule, there is no tenderness of the vertebræ, and but exceptionally the disease is complicated with spinal irritation. Rachialgia is no conspicuous symptom, and of the sensory nerves only those of the head are involved. Nutrition is impaired, and loss of flesh is considerable. The psychical faculties are affected. Although intelligence may be preserved there is weakening of the memory and confusion of ideas, and the result is a considerable diminution of the capacity for mental labor. There is disturbance of sleep, even insomnia. But the most apparent symptom is the lack of muscular endurance.

From an ætiological point of view a hereditary disposition to neuroses is first of all to be mentioned. Among the exciting causes which produce nervous exhaustion, grief, mental distress, overwork, excesses in venery, and seminal losses play the most conspicuous rôle. *Overlactation* is sometimes a cause of neurasthenia, but it is not always easy to determine whether under such a contingency we have to deal with anæmia or neurasthenia. I have seen a young married lady with most alarming symptoms of nervous prostration, which came on during lactation, and yielded readily to weaning the child and a ferruginous treatment. In her case the differential diagnosis was established by a microscopical examination of the blood, which excluded anæmia.

The *treatment* of neurasthenia must consist of rest, abstinence from emotional excitement, and from mental and physical work. Besides a sojourn in the country, along with avoiding fatigue or long walks, the application of general faradization offers the quickest and surest chances of recovery. It is in neurasthenia that I have had the best results from the method of applying the interrupted current, first practiced and described by Beard and Rockwell, and designated by them as general faradization.

II. SPINAL IRRITATION.

If in *neurasthenia* we noticed that the most predominant symptoms were those of *depression*, we see in spinal irritation those of *irritation*. The most prominent symptom is dorsal pain, which appears especially after exertion and fatigue, but is hardly ever wanting (Rosenthal). Generally, several vertebræ are tender, which tenderness, however, is stable, and not varying, as in the symptomatic form. This painful region is acutely sensible to slight mechanical irritations, such as the application of electricity or heated water. The rachialgia is increased through any exertion, especially flexion of the trunk (Rosenthal), and the patients are apt to mistake this pain for pain in the kidneys. There are, besides, unlike neurasthenia, neuralgias in different parts of the body, cervico-occipital, intercostal, facial, lumbar, abdominal and crural; there are cephalalgia and nausea, besides numbness in the lower limbs, and sensations of burning and sometimes of cold. Again, there are serious motor disturbances, as muscular contractions, which are very distressing, and occurred in two of my cases especially in the muscles of the neck and calf. In true spinal irritation, as in neurasthenia, *but unlike* symptomatic spinal irritation, or rather pelvic rachialgia, we meet generally with emaciation of our patients; the features are pinched, there is an expression of suffering and of anxiety. If we say that neurasthenia is amenable to treatment, we have to state that spinal irritation gives a far worse prognosis. That there is an organic lesion of the spinal column in spinal irritation, either hyperæmia or anæmia, seems to be accepted by most authorities except Leyden. Again, if we may depend upon the assertions of some that spinal irritation runs into tabes occasionally we must certainly believe it to be an inflammatory process, a surmise that is strengthened by the fact that local antiphlogistics, as cupping, leeching, counter-irritants, often bring about relief.

Treatment. A hot douche to the spine daily employed along with the administration of tincture of aconite root (two drops every three hours), or five drops of gelsemium every four hours (Bartholow, spinal hyperæmia) are the most efficient means. The latter author remarks: "In all cases of spinal hyperæmia the cause must be removed." But can we do this always? I hold that spinal irritation is mostly hereditary, and of course we cannot remove heredity. The most powerful remedy at our hands to improve the faulty circulatory conditions of the spinal column is, after all, galvanism, and a descending stabile galvanic current has produced more good in my hands than any internal remedy.

III. PELVIC RACHIALGIA.

This term, I am aware, does not fully cover the whole field of symptoms which I am about to group together as a disorder, — distinct from, although resembling, spinal irritation, — and the term *symptomatic* or *pseudo*-spinal irritation might for this reason be more appropriate. But as *rachialgia* is by far the most prominent symptom, and originates from and follows the underlying pelvic disturbances, and the word spinal irritation, even when qualified by the reassuring prefix *pseudo* or *symptomatic*, is so vague, misleading, and shocking to the sensibilities of physician and patient alike, I adopted this term as it stands. Pelvic rachialgia, then, is a complex of symptoms generally designated by the authors as spinal irritation with depression. But these symptoms constitute, as we have seen, no distinct, separate disease of the spine, but are the expression of an organic lesion of the pelvic organs. I omit to relate cases illustrative of this point, and offer to your kind consideration but my honest conviction, gained from observation of a great many cases, in which it was evident that the so-called symptoms of spinal irritation never appeared *before* the affection of the prostate, the ovaries, the uterus, or the urethra, and that they were constantly accompanying the pelvic disorders, although it must be admitted that a hereditary disposition to neuroses in general favored the appear-

ance of the spinal sympathy. If, on the other hand, a cessation of the spinal irritation coincides with the cessation of the pelvic disorders, we must certainly come to the conclusion that the sympathetic symptoms of the spinal cord, as rachialgia, burning sensations in the lumbar region, general languor, are typical and characteristic symptoms of pelvic organic disease just as much as a mucous discharge after defecation or micturition is of prostatitis or leucorrhœa of cervicitis. If in studying real spinal irritation we have noticed that, as in neurasthenia, loss of flesh, even emaciation, is likely to be present, that the expression of the face denotes a considerable degree of suffering, a suffering stabile and constant; again, that the appetite is poor and sleep disturbed, we find in pelvic rachialgia that the *appetite is good*, and that the patients have a healthy and plump appearance, a circumstance that induces the friends, and often even the attending physician, to think that the symptoms complained of are either imaginary, exaggerated, or simulated. There is besides, as already stated, a considerable difference in the *result* of *treatment* between spinal irritation and pelvic rachialgia. In the former violent bodily exercise increases the trouble, and rest and tonics give good results. In the latter rest is injurious, tonics give a negative result, but saline aperients and bodily exercise give, as a rule, astonishing success.

I have at present a patient suffering from incurable chronic prostatitis, whose distress and despondency for the last ten years has been pitiable indeed, as his rachialgic symptoms, as lumbar pain and burning, languor, irritability, and nervousness, had not been mitigated either by tonic, hydropathic, or electrical treatment, who instinctively takes some kind of physical exercise and experiences instantaneous relief from his nervous irritation. Under the head of these exercises I name ten-pin rolling, billiard playing, horseback riding, and walking. That the transitory good result of these physical exertions must depend upon disengorgement of the prostatic gland, brought about by removing venous stasis or congestion, I do not doubt for a moment. An important difference between real spinal irritation and the feigned form (pelvic rachialgia) is, that the symptoms of the latter are *evanescent*. Thus you are apt to see such patients in the most changeful state and disposition of body and mind, now exultant and joyful, elastic in their actions, free from pain, with a complexion ruddy, with eyes beaming and reflecting happiness and high spirits, only to relapse after the act of micturition or defecation into a fit of exhaustion, suffering, despondency, or distress. As also in pelvic rachialgia the spinous processes, especially of the lumbar vertebræ, show a decided tenderness, but, as I very often observe, during the interval of comparative well feeling this tenderness is entirely wanting. It is interesting to study how with the reappearance of the pelvic irritation this tenderness recurs at once, and along with it the entire train of symtoms of irritable weakness.

Cephalalgia or other neuralgias and *insomnia* I rarely meet with in pelvic rachialgia. On the contrary, patients sleep generally long, are inclined to be indolent, and excuse their laziness by stating that they feel better whilst in bed. But this comfortable feeling in bed is but apparent, for during rest in bed there is no desire to micturate or defecate, the pelvic organs are at rest, and there is hardly any congestion. Hence a pause in the rachialgic symptoms.

But as soon as the patient after rising goes to stool, the prostate, riding as it were on the rectum, is getting pushed or pulled along by the movement, and this irritation is at once transmitted to the lower parts of the spine, to be followed by nervous prostration, burning, tenderness of the vertebræ, and so on. How these symptoms are produced, whether by disturbances of circulation within the spinal column, due to temporary paresis or stimulation of the vaso-motor nerves, or by reflex action, I am not prepared to state.

The prognosis as to an ultimate radical cure in pelvic rachialgia is not favorable, as only with a cessation of the pelvic disorders a perfect cure can be expected, and these very diseases are rarely eradicated. But an amelioration of the distressing symptoms to the extent even of a rather comfortable existence can with safety be promised the patient.

As the most successful *treatment* of pelvic rachialgia I consider the administration of drachm doses of sulphate of magnesia before breakfast three to four times a week, cold ablutions of the lumbar and hypogastric regions, and moderate bodily exercise, as gymnastics, horseback riding, billiard playing, and so on. Furthermore, I find celibacy on the one hand and excesses in venery on the other injurious, but a very moderate and judicious performance of the sexual functions beneficial.

RECENT PROGRESS IN PATHOLOGY AND PATHOLOGICAL ANATOMY.

BY WILLIAM F. WHITNEY, M. D.

A CONTRIBUTION ON THE FORMATION OF GIANT CELLS IN EPITHELIAL TISSUES.[1]

MUCH has been done of late in the investigation of giant cells, and differences of meaning have arisen as to their manner of formation, their origin, their value, and the soil from which they spring.

In regard to their formation, it is supposed that they came either from a single cell alone or by the addition of protoplasm from the neighborhood, or from the union of many cells.

Their origin has been assumed to be from white blood corpuscles, from granulation tissue, from endothelium, and from epithelium.

A different value has been assigned to them. In part they are considered as a product of progressive, in part as an expression of retrograde, metamorphosis. To the first group are reckoned the cells of this class occurring normally in the bone marrow as well as those arising in granulation tissue and in sarcomas, while those in lupus and tubercle appear to many authors to belong to the second group.

They come in very different tissues. Normally they are found in the bone marrow, in the reabsorption of bone, in the placenta, and in the uterine sinuses at the insertion of the placenta. In pathological processes they occur repeatedly. Here the nuclei are colored less distinctly, and are only to be recognized by their faint contour; this finally disappears, and with it the nucleus, and there only remains a glancing scale.

In epithelial growths the protoplasm in which these nuclei lie corresponds with that of the epithelial tongues, and is either granular or homogeneous. It has no peculiarities in respect to coloring agents, except at times it does not color at all, suggesting a fatty degen-

[1] Klauss, Virchow's Archiv, vol. xcv., p. 249.

eration. The shape of the cells varies greatly. Among the smallest there is a form corresponding to flat epithelium, while the larger ones have no type. The first can often be seen in the periphery of the tongues, and occasionally they are found occupying an entire cross section. For these cells there is no doubt of their origin from epithelium. On the other hand, when these cells lie in the periphery they are either directly connected with it or separated from it by a narrow space. In the latter case they appear as polyformed protoplasmic masses corresponding in size to several epithelial cells, to which they probably correspond. Finally, giant cells are found in the round cell tissue, but their nuclei and protoplasm correspond with those previously described.

Whether these cells are formed by confluence of other cells, or whether from nuclear division or from a combination of both processes, is to be considered. In support of the confluence theory there is to be brought forward their irregular form, the atypical position of the nuclei, the degenerative processes which they undergo (calcification, or change into hyaline scales), and finally the fact that a faint contour is still visible in many of the larger cells. In other cases where round or oval protoplasmic masses can be made out, in the midst of which are fine vesicular nuclei, the division of the nuclei must be assumed.

The essential results of these observations, which were made on over seventy cases of epithelial new growths, were: —

(1.) In epithelioma there occur giant cells which are derived from the epithelial cells.

(2.) No certain conclusion can be drawn as to the manner of their formation.

An interesting fact was the production of giant cells along a piece of catgut which had been used at a primary operation and was removed with the recurrent growth.

In an adenoma of the sebaceous glands, a very rare form of growth, and essentially an epithelial structure, giant cells were also present.

INVESTIGATIONS ON THE CICATRIZATION OF THE INTIMA AND MEDIA OF ARTERIES AFTER LIGATURE.

Zahn [1] has made a series of observations upon the healing of the media and intima of vessels after rupture. He was led to this by a case of aneurism, in which this had evidently taken place, and where it seemed that the material for restoration was formed from the endothelium without the aid of the elastic or connective tissue.

The experiments to prove this consisted in the partial ligature of the carotid or femoral of rabbits. A silk thread was passed round the vessels and tied; after a time, varying from thirty seconds to one minute, the the knot was loosened and the blood allowed to resume its course. Sometimes one and sometimes two ligatures were placed about the vessel. In the latter case the peripheral was always loosened first in order to prevent the sudden pressure from causing an extravasation of blood between the coats.

In a few cases the external surface was covered with cinnobar. The wound made by the operation quickly healed by first intention.

The animals were killed after varying times either by puncture of the medulla or by bleeding. The skin was quickly removed, and the artery carefully loosened from the surrounding tissue for a considerable distance. A piece of pith was placed beneath the vessel, which was pinned to it. The whole was then removed, and the artery laid open with a fine pair of scissors. The internal surface was washed with a small stream of distilled water, then covered for a few minutes with a one half per cent. solution of nitrate of silver. The specimen was hardened in alcohol and imbedded in celluloid.

The specimens from the third or fourth day after ligature were prepared by first washing with a three fourths per cent. solution of common salt, then for fifteen to thirty minutes in a five per cent. solution of nitric acid. After this a weak solution of alum was poured over them and then immersed for twenty-four hours in a solution of alum carmine. Afterwards hardening in alcohol.

As the result of the examination of these preparations it appeared there was no formation of a thrombus after tearing the intima through entirely and partially rupturing the media. During the first or second day rather more red and white corpuscles were found on the irregular edges of the rent than elsewhere on the surface of the vessel, but never in sufficient numbers to form a real clot. Further, the rest of the media and the externa were sufficiently strong to withstand the arterial pressure and thus prevent an aneurismal dilatation.

The most important rôle in the process of repair is played by the intima. In the neighborhood of the edges there is a marked formation of new cells. In places these lie one over the other and push towards the opening, first covering the sides and then the bottom of the tear. By their further increase they fill up the hole entirely, and then appears between them a homogeneous substance replaced later by a fibrillar connective tissue. Thus the cicatrization proper is brought about by the endothelium alone, the other tissue elements taking no part in it.

In consequence of the force applied to the outside of the vessel there is a reactive hyperæmia of the adventitia, with an infiltration of round cells, which later assume a spindle shape. They never, however, penetrate deeper than the external coat, and cannot therefore have anything to do with the repair of the inner coats.

(To be concluded.)

Reports of Societies.

THIRTY-FIFTH ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

First Day's Proceedings.

The thirty-fifth annual meeting of the American Medical Association opened in Washington, Tuesday morning, May 6th, at eleven o'clock, at the First Congregational Church, about one thousand delegates being present.

The first session was called to order by Dr. A. Y. P. Garnett, Chairman of the Committee of Arrangements. Prayer was offered by Rev. John H. Elliott, and the address of welcome was then delivered by Dr. Garnett, who dwelt upon the appropriateness of Washington as a centre for such gatherings of a national character, and predicted its increasing importance and attractiveness as a city.

ANNUAL ADDRESS BY THE PRESIDENT.

DR. AUSTIN FLINT, President of the Association, was received with much enthusiasm upon rising to deliver the annual address. The first part of his address was a review of the history of the Association, and his subsequent remarks were especially devoted to a consideration of what had been done in the past to elevate the standard of medical education and of professional dignity, and of what remained to be done in the early future.

He expressed his conviction of the necessity of endowments for the establishment and maintenance of high standards in medical schools. During the preliminary education previous to the study of medicine every student ought to gain a thorough knowledge of the more liberal arts and sciences. The study of the dead languages is not so essential to a medical education as the study of physics, of biology, and of the French and German languages.

There are some colleges, Dr. Flint acknowledged, which may be guilty of flagrant abuses, which do injustice to students seeking a higher standard of medical knowledge, by allowing other students to gain a knowledge of the profession cheaply and too hastily. In an experience, however, of forty years among medical students, he was prepared to say that they compare favorably with students of the other sister professions.

In the standard of medical education he had no disposition to apologize for some abuses and evils complained of by brother professors. A large number of medical colleges place their reliance upon State legislation, which is delusive. Some private colleges are deficient in their means of instruction, and lack the requirements for giving a proper and thorough medical education. Our duty is to promote more and more and elevate our profession, and to do this the profession must rely upon itself, recommending changes and improvements in certain measures of immediate practicability. In this the National Association must take the initial step, at the same time coöperating with the medical colleges, with an earnest desire for harmonious views and united action, to secure uniformity in the different States, and opposing all differences. To this end he suggested that a standing committee be appointed upon the uniform action of medical colleges. It is not to be expected that all of these desirable improvements can be accomplished at once, but with earnest efforts the result of a higher standard of medical education can be achieved through a board of examiners not engaged in medical education.

Dr. Flint then referred to the usefulness of the medical profession, the manifold difficulties and peculiarities of the calling. In order to practice the profession a physician must both honor himself and the profession. The same Code of Medical Ethics which was adopted in 1847 at the convention held in Philadelphia is still held intact by the medical societies throughout the United States except in New York. The excellence of the Code has produced a salutary influence upon the lives of the profession, and far more so than the medical ethics of any other country. The opposition to this Code involves both a question of taste and of principle. It forbids consultation with irregular practitioners, and presumes that every practitioner must possess the professional ability and requirements of a physician, who has received a regular education, and who does nothing that is prejudicial to the honor and usefulness of the profession.

Continuing, Dr. Flint alluded to the humane principles of the profession and its higher laws of philanthropy. He referred to the advancement in the diffusion of medical knowledge through the medical journals, and the work done by the several Sections.

Referring to the International Medical Congress of 1887, Dr. Flint thought it should be held in this country rather than at Copenhagen. He feelingly alluded to the serious illness of Prof. Samuel D. Gross, of Philadelphia.

In conclusion, Dr. Flint spoke of the great advantages to be derived from the American Medical Association meeting in Washington, where the Army Medical Museum and a medical library, the largest, most valuable, and most practical in the world, were at hand. He hoped that Congress would provide for the erection of a new library building in which this valuable medical collection could be safely stored. Here also was the National Museum and the Department of Agriculture, all of which were of interest to the delegates.

Dr. Flint was frequently applauded during his address, at the conclusion of which

DR. JOSEPH M. TONER, of Washington, moved that a telegram be sent to Prof. S. D. Gross, of Philadelphia, informing him of the sympathy felt for him by the Association in his illness and of its hopes for his speedy recovery. This was unanimously adopted.

DR. SAYRE, of New York, moved that that part of President Flint's address relative to the International Medical Congress of 1887 be referred to a special committee of five with Dr. Billings as chairman, and the motion was adopted.

A motion by DR. QUIMBY, of New Jersey, that 5000 copies of the President's address be printed, was also adopted. That portion of the address concerning the subject of Medical Ethics was upon motion of Drs. Garcelon of Maine, and Ferguson, of New York, referred to a committee of seven, to report upon its recommendations as soon as possible.

ANNOUNCEMENTS.

Announcements were made of certain papers submitted to be read before the Association upon State County Hospitals by Dr. Suttens, of Aurora, Ind.; one by Dr. Theobold; another by Dr. John T. Roberts, upon the Use of the Trepan in Head Injuries; another by Dr. Walter Wyman, U. S. A., in charge of the Marine Hospital Service in Baltimore, upon Hospitals, etc.

The announcement was made that the various delegations would meet in different portions of the auditorium and galleries of the church after adjournment for the purpose of nominating one member from each delegation to form a nominating committee upon officers to be elected for the ensuing year.

The Association adjourned at 1.30 P. M., to reassemble at ten o'clock the next morning.

MEETING OF SECTIONS.

After the adjournment and at 2.30 o'clock the different Sections met. Those of the Practice of Medicine, Physiology, Obstetrics and the Diseases of Women, on Ophthalmology, Otology, and Laryngology, and on Diseases of Children, meeting in different portions of the church; the Section on Surgery at the armory of the National Rifles; and the Sections on Oral and Dental Surgery and State Medicine at Medical Society Hall, southeast corner of Sixth and F Streets.

The first Section, on the Practice of Medicine, Dr. John V. Shoemaker, chairman, listened to papers by Drs. Austin Flint, Sr., Edward Janeway, New York, Louis A. Duhring, of Pennsylvania; Whittaker, of Cincinnati; Black, of Illiuois; and Traill Green, of Pennsylvania. In this Section several papers were passed over for want of time.

The second Section, on Obstetrics, Dr. T. A. Reamy, of Cincinnati, President, carried out its full programme, papers being read by Drs. Sutton, of Pennsylvania; Campbell, of Georgia; Polk, of New York; Byford, of Illinois; Joseph Taber Johnson, of the District of Columbia; and Jenks, of Illinois.

The third or Surgical Section, Dr. C. T. Parks, of Chicago, chairman, heard one paper by Dr. Fred. S. Dennis, of New York, and on the announcement of the death of Professor Gross, of Philadelphia, adjourned until the next day.

The fourth Section, on Public Health, Dr. Deering J. Roberts, of Tennessee, chairman, and Dr. Franzoni, District of Columbia, secretary, listened to papers by Dr. Leffmann, of Pennsylvania, and C. H. Von Klein, of Ohio.

The fifth Section, Dr. J. J. Chisolm, of Baltimore, chairman, heard papers by Drs. Keyser, of Pennsylvania; Risley, of Pennsylvania; Williams, of Ohio; and Seiler, of Pennsylvania.

Papers by Drs. Woodbury (Pennsylvania), Duncan (Missouri), and Brown (New York) were read before the sixth Section (Diseases of Children), of which Dr. William Lee, of Baltimore, is chairman, and Dr. G. N. Acker, of Washington, secretary.

The Section on Oral and Dental Surgery, Dr. T. W. Brophy, of Chicago, chairman, and Dr. John S. Marshall, of Chicago, secretary, heard a paper by Dr. Jacob H. Williams, of Boston, and adjourned.

RECEPTION AT THE WHITE HOUSE.

In the evening the Association was received by the President of the country at the White House. The arrangements were as elaborate as for any official reception of the winter. The suite of state apartments on the ground floor was open and decorated, and, in addition, almost all of the rooms of the second floor were thrown open to the guests. The Marine band was stationed in the vestibule, and at half-past eight struck the first chords of "Hail to the Chief" as the receiving party descended the stairway and entered the blue parlor. In addition to the thousand members of the Association in the city, many of them accompanied by their wives, many government officials and others were present by invitation of the President. Secretaries Frelinghuysen, Lincoln, and Chandler, Postmaster-General Gresham, Attorney-General Brewster, and Secretary Teller were in the blue parlor back of the receiving party.

Upon leaving the White House the members, accompanied by their families, repaired to the residence of Mrs. L. Z. Leiter, corner of P Street and Connecticut Avenue, where a very handsome reception was given them. This reception lasted until after midnight.

SECOND DAY'S PROCEEDINGS.

The American Medical Association reassembled Wednesday, June 7th, at the previous place of meeting at ten o'clock A. M., and prayer was offered by Rev. W. A. Bartlett, D. D.

DEATH OF PROFESSOR GROSS.

The President announced in a few suitable words the death of Prof. S. D. Gross, which took place in Philadelphia the previous afternoon. Dr. Gross was formerly President of the Association, and his name evoked some eulogistic remarks.

A committee, consisting of Drs. Austin Flint and L. A. Sayre, New York; Drs. Packard, Pennsylvania; F. H. Hamilton, New York; Moses Gunn, Chicago; W. T. Briggs, Tennessee; and I. M. Hayes, Pennsylvania, was appointed to draft resolutions of respect to the memory of the deceased.

APPOINTMENT OF COMMITTEES.

The committee of seven to which was referred the President's address was named, as follows: Drs. N. S. Davis, W. W. Dawson, W. T. Briggs, D. W. Stormont, T. F. Prewitt, J. L. Cabell, and H. B. Ransom.

It having been suggested that the next International Medical Congress — that of 1887 — ought to be held in the United States, the following gentlemen were appointed a Committee on Invitation: Drs. J. S. Billings, Washington; L. A. Sayre, New York; R. H. Fitz, Boston; I. Minis Hays, Philadelphia; Henry F. Campbell, Georgia.

The following Committee on Nominations was appointed: Jerome Cochrane, Alabama; P. O. Hooper, Arkansas; J. W. H. Lovejoy, District of Columbia; H. Galloway, Dakota; Jesse Harris, Colorado; G. L. Porter, Connecticut; W. Marshall, Delaware; F. W. Hatch, Jr., California; E. P. Cook, Illinois; T. B. Harvey, Indiana; H. C. Huntsman, Iowa; F. T. Dickman, Kansas; W. H. Wathen, Kentucky; T. G. Richardson, Louisiana; F. C. Thayer, Maine; J. S. Lynch, Maryland; B. A. Duncan, Mississippi; D. Leasure, Minnesota; Charles A. Savory, Massachusetts; N. F. Essigs, Missouri; C. J. O. Hagner, North Carolina; J. W. Parsons, New Hampshire; H. F. Lester, Michigan; S. F. Merser, Nebraska; J. W. S. Gouley, New York; J. Parish, New Jersey; W. M. Beach, Ohio; J. B. Murdock, Pennsylvania; J. H. Eldridge, Rhode Island; W. Huger, South Carolina; J. H. Pope, Texas; Duncan Err, Tennessee; Alexander Harris, Virginia; H. D. Holton, Vermont; George Beard, West Virginia; William Fox, Wisconsin; J. R. Smith, United States Army; N. L. Bates, United States Navy; Walter Wyman, United States Marine Hospital Service.

MEDICAL AND SANITARY SERVICE ON PASSENGER VESSELS.

DR. A. N. BELL, chairman of the committee appointed upon the resolution for securing more competent medical and sanitary service on board trans-oceanic passenger vessels, submitted a report. He stated that after due consideration a bill was prepared and placed in the hands of Hon. H. W. Slocum, who had introduced it in the House, and it had been referred to the Committee on Commerce. The bill To Regulate the Carriage of Passengers by Sea provides that in all such vessels two compartments shall be provided exclusively to be devoted to hospital uses, one for men, and one for women. It requires the employment of a medical practitioner, and when the number of passen-

gers exceed six hundred he is to have an assistant. The doctor is to report to the captain such regulations as he wishes carried out.

The report of Dr. Bell elicited a discussion which was participated in by Dr. Kaiser, of Philadelphia, Dr. Irwin, of New York, and Dr. Jones, of Pennsylvania. Dr. Kaiser thought that the bill was a good one, but it did not go far enough, as it should require the surgeon of the vessel to report directly to the United States government, and not to the captain of the vessel. Dr. Irwin said that owing to the fact that the bill allowed the surgeons to be appointed by the company, and to be under their control, it was impracticable. He favored the plan of making the surgeon independent of the company, and in all sanitary matters subject only to the laws of the United States. Dr. Jones said that from his position as a government medical inspector he had never found that captains of our vessels interfered with sanitary regulations, or that the hospitals of those vessels were occupied with rope and waste matter. The report of the committee was accepted, and the committee continued.

A resolution urging upon Congress immediate action in the matter was adopted.

THE BACILLUS TUBERCULOSIS AND THE GERM THEORY.

DR. J. V. SHOEMAKER, chairman of the Section on the Practice of Medicine, read his Report, treating especially of the Bacillus Tuberculosis and the Germ Theory of Disease. After a few preliminary remarks in regard to the difficulty of his subject in consequence of the new theories constantly advanced, he said that in the field of pathology and pathological research the study of the infinitesimal has attracted great attention; and of the subjects prominently brought to the attention of the profession, and exciting more universal interest than any other, is the bacillus of tuberculosis and its contagious character. The causal relation of the bacillus to the disease was still an open question. Typhoid fever, yellow fever, and cholera were considered in their relation to the germ theory. Trichinosis was touched upon, and the reader defended American pork against the aspersions cast upon it by European governments, claiming that trichinosis with us is a very rare disease in comparison with its frequent occurrence in Europe. In conclusion Dr. Shoemaker referred to the tendency manifested on the part of specialists to form cliques and separate associations, and to exclude the rest of the profession from their deliberations, which the speaker characterized as an attempt to form an aristocracy in the most democratic of professions. Outside organizations on special subjects, said the speaker, will detract from the interest and advantages of our meetings, and the younger members, neglecting the general subject of medicine, dazzled by the apparent brilliancy of a select few, will wander forth to ultimately destroy their own usefulness.

These remarks were loudly applauded.

DR. T. A. REAMY, of Ohio, chairman of the Section on Obstetrics, read instead of a Report a paper upon the Operations for Laceration of the Cervix Uteri.

Drs. Buford and Stevens, representatives of the Canadian Medical Association, were invited to seats on the platform.

An invitation was read from the managers of the New Orleans Cotton Exposition for the Association to hold its next meeting in one of the rooms of the Exposition Building.

LEGISLATION RELATING TO VIVISECTION.

DR. HENRY SMITH, of Philadelphia, offered a resolution opposing legislation restricting the practice of investigation in medical science by experiments on animals, and asking the appointment of a standing committee for this purpose.

DR. DALTON said that the proposed legislation was aimed at vivisection and originated with the Anti-vivisection Society. It would prevent a professor from showing his class the process of digestion, or the circulation of blood in a frog's foot. The medical profession would coöperate with the society in preventing needless cruelty. The resolution was referred to the following committee: Drs. H. C. Wood, William Pepper, James Tyson, of Pennsylvania; Christopher Johnson, Maryland; J. C. Dalton, Austin Flint, Jr., of New York, and J. S. Billings, United States Army.

MEDICAL COLLEGES.

DR. ATWOOD, of St. Louis, offered a resolution, objecting to the general advertising of medical colleges as tending to increase the number of scholars and lower the standard.

DR. BENJAMIN, of Maryland, followed with an additional resolution, urging upon all medical colleges the necessity of elevating the standard of education, at least so far as to require a preliminary examination, a three years' course, a registry of attendance and practical demonstrations of diagnostic skill.

Debate on the resolution being agreed to, DR. HENRY, of New York, expressed his emphatic disapproval of the manner in which the medical colleges were disgracing the profession on account of the incompetent doctors which they graduated. This remark was greeted with applause and a few hisses. Dr. Henry replied warmly that there was no use in hissing, for he knew that those who hissed had private axes to grind. The resolution of Dr. Benjamin was finally adopted, and the Association adjourned shortly after one o'clock until ten the next day.

MEETING OF SECTIONS.

During the afternoon the various Sections met in the church, Medical Society Hall, and Rifles' Armory. The Section of Surgery and Anatomy met at the latter place, a large attendance being present. A resolution of respect to the memory of the late Dr. Gross, of Philadelphia, and highly eulogistic of his learning and skill, was reported by a committee consisting of Drs. J. M. Keller, chairman; Lewis A. Sayre, Austin Flint, Jr., and R. A. Kinlock, and was unanimously adopted. A paper on Railroad Injuries of the Extremities of the Human Body was read by Dr. T. R. Varick, of New Jersey. An address was delivered on Spontaneous Fracture of Calculi by Dr. Gouley, of New York. The discussion on this paper was participated in by Drs. J. Ford Thompson, of Washington; Hutchinson, of Brooklyn; Sayre, of New York; Prewitt, of St. Louis; Pollock, of Pennsylvania; Dawson, of Ohio; and others. Papers by Dr. C. A. Wheaton, of Minnesota; Dr. Joseph Ransohoff, of Ohio; and Dr. A. Pearce Gould, F. R. C. S., were read by titles only, after which the Section adjourned.

The Section on the Practice of Medicine listened to a paper entitled A Contribution to the Clinical Study of Epilepsy, by Prof. William Pepper, of Pennsyl-

vania, which was discussed by Dr. Eugene Grissom, of North Carolina, and others. Dr. Flint also read a paper, but the programme which had been prepared could not be followed for want of time. The Section on Children's Diseases heard a paper by Dr. J. W. Brown, of New York, on Diphtheria, and papers by Dr. Atlee, of Pennsylvania, and others. The Section on Obstetrics heard papers by Dr. Theophilus Parvin, of Pennsylvania, Dr. A. Reeves Jackson, of Illinois, Dr. William H. Taylor, of Ohio, and others. Dr. Engelman, of Missouri, and Dr. Campbell, of Georgia, participated among others in the discussion. Dr. B. N. Towle, of Massachusetts, read a paper before the Section of State Medicine. Papers were read before the Section of Ophthalmology, Otology, and Laryngology, by Drs. Fulton, of Minnesota, Rankin, Little, and Turnbull, of Pennsylvania, and others. The Section on Aural and Dental Surgery heard papers by Dr. Edward C. Briggs, of Massachusetts, and Dr. A. W. Harlan, of Illinois.

RECEPTION AND BANQUET.

In the evening the delegates were given a reception and banquet by the Medical Association of the District of Columbia at the armory of the National Rifles, on G Street, between Ninth and Tenth Streets northwest. At least two thousand persons, delegates to the National Convention and their wives, were present. Drs. A. Y. P. Garnett, chairman of the Committee of Arrangements, and Dr. D. C. Patterson, were in charge of the entertainment. Music was furnished by the Marine band, and dancing was kept up until about midnight. The floor committee consisted of Drs. S. S. Adams, McArdle, L. L. Friedrich, Clarke, Patterson, G. S. Magruder, H. D. Frye, and Frank Hyatt.

SUFFOLK DISTRICT MEDICAL SOCIETY.

SURGICAL SECTION.

S. J. MIXTER, M. D., SECRETARY.

MARCH 5, 1884. DR. C. B. PORTER reported a case of

EXCISION OF A PORTION OF INTESTINE, INCLUDING PART OF THE ILEO-CÆCAL VALVE FOR THE CURE OF FÆCAL FISTULA IN RIGHT GROIN.[1]

The reader showed several dried specimens, illustrating the anatomy of the parts involved and the portion of intestine that had been removed.

DR. CHADWICK said that he had never excised a portion of the intestine, but had had a case of tear during ovariotomy. The edges were brought together without attempting to bring the serous surfaces in apposition. Union did not take place. The possibility of washing out the intestine above and below the seat of operation in these cases, by means of a long flexible tube, was also spoken of.

In answer to a question asked by Dr. Harrington, DR. PORTER said that his treatment of abdominal wounds in the future would, perhaps, be somewhat influenced by his success in this case. In cases of pistol-shot wounds, and some other penetrating wounds where there was no certainty of escape of fæces into the abdominal cavity, it would be much better to wait until some symptoms of such a condition were present before opening the abdomen.

DR. MIXTER said that this was the first case on record where it had been stated that the ileo-cæcal valve had been excised. The difficulty experienced in uniting the large and small intestine in this case was similar to that found in uniting the stomach and duodenum after excision of the pylorus. On looking up the literature of the subject, one is struck by the fact that in almost all the cases where death has followed the operation the wound in the intestine has been found on autopsy to be thoroughly united by plastic lymph even where the patient has died from shock a few hours after the operation. Fatal results seem to be due principally to shock, which is, of course, especially to be feared in cases of long-neglected strangulation and gangrene, or else due to septic processes started by escape of fæcal matter at the time of operation into the abdominal cavity. If the operation has been performed antiseptically, and the cut ends of the intestine carefully united in the proper manner, a good result may be expected.

A general discussion on the liability of abdominal hernia as a result of laparotomy followed.

In reply to Dr. Chadwick, DR. GREENE stated that he had seen several cases, seven or eight, where this condition had resulted. These herniæ were very difficult to keep in place, the best apparatus being a well-fitted abdominal belt with firm padding. Good support should be ordered for some time after operation.

DR. CHEEVER spoke of the use of silver wire in the reported case in uniting the edges of the abdominal ring. In many cases silver wire is retained and causes no trouble, but in others it is a constant source of irritation until it is discharged. The latter seems to be most often the case when it has been used in a situation where it is subjected to pressure, or to constant movement.

DR. DOUGLAS GRAHAM read the following extracts from a letter received from a patient who is afflicted with

BRITTLE BONES.

"I will now try to tell you what I can about my numerous accidents. The whole number of breaks is eighteen. I can remember fourteen of them. Mother thinks the first was the left arm at the elbow, caused by stumbling against the stove zinc when I was eighteen months of age. Then occurred a few breakages about the location of which we are uncertain. After these came a fall from a chair, breaking my right collar-bone, which I remember very well, although then hardly three years old. At four years of age stepped backward from a door-step, breaking my left leg between the knee and ankle. Before I was five, fell on the carpet and broke right elbow. A few months afterwards broke right elbow again. At eight had broken each arm again at the elbow, one of these caused by a fall from a swing, and the other at school. As soon as possible after these breaks I slipped on a wet plank and broke right leg between knee and ankle. Before this was well I tried to walk a little while mother was out and broke the same leg again at the same place. When a little past nine years of age I fell on a stone sidewalk and broke the right elbow, or rather the ends of both bones about one inch below the joint, dislocating them, and injuring the shoulder so that I can still turn my arm with the point of my

[1] See page 457 of this number of the JOURNAL.

elbow in front. It was not set, but makes a useful arm after all.

"I had no more accidents, except a sprain or two, until I was thirteen, when a little dog ran against me and then I fell on the pavement and broke my left collar-bone and some other bone about the shoulder. At fourteen broke one of the bones between the elbow and wrist. At eighteen fell through a hole in the sidewalk and broke the point of right elbow, and this made quite an improvement in the looks of it. At eighteen a mischievous horse chased me. I ran, and on reaching the plank walk stepped so quickly that my left ankle was broken through the joint. That was the worst break I ever had, and I was lame a long time after it.

"These are all the accidents I can remember. Mother kept an account of the number. The summing up is: —

"The right arm, broken nine times; the left arm, twice; left leg, three times; right leg, twice; right collar-bone, once; left, once. Total, eighteen.

"I used to be extremely lame and suffer very much on going to school, especially in winter when the walking was rough by reason of ice, or any inequality of surface, and any slight twist or wrench of my limbs would cause extreme pain. Since I have attained my growth I have been much better, and I have met with no accident for fourteen or fifteen years, except while in Boston I sat down before I was quite ready.

"It may be of interest to you to know that my father broke his bones fourteen times, a cousin of his twenty-one times, and the latter suffered from breaks after he was quite an old man. My father's paternal uncle was also a bone breaker."

NEW YORK ACADEMY OF MEDICINE.

AT a stated meeting of the Academy held Thursday evening, May 1st, DR. J. G. ADAMS read a Memoir of E. L. Beagle, M. D., after which DR. MARY PUTNAM JACOBI read a paper entitled

SOME CONSIDERATIONS ON ENDOMETRITIS.

She started out with the proposition that the endometrium was the essential part of the utero-ovarian system. The two cycles, the greater one of pregnancy, and the lesser one of menstruation, peculiar to this germinal membrane, were, she claimed, completely homologous, and endometritis always had its origin in subinvolution following the one or the other of these cycles. Parenchymatous metritis, again, always depended on disease of the mucous membrane, while nearly all utero-ovarian disorders could be traced to the same origin. The ultimate aim of all treatment in this class of affections was, therefore, the restoration to its integrity of the menstrual cycle, and for both the success and the safety of the measures employed it was essential that the rhythmical character of this process should be taken into consideration.

In view of these considerations a slight uterine catarrh became a matter of great significance. A diseased condition was not to be studied as an isolated fact, but in relation to its origin, connections, and possible results; and it was because the tissues of the highest function were always the first to become affected in any pathological process that endometritis was the original factor in utero-ovarian disease, and that it assumed such grave importance. Dr. Jacobi then advanced the hypothesis that at the time of menstruation the accumulation of blood in the periuterine and ovarian plexus of veins caused new growth in the lining mucous membrane of the uterus, and that this development of the endometrium continued (unless pregnancy occurred and the greater changes peculiar to its cycle resulted) until the new growth was arrested by pressure, which finally resulted in the rupture of vessels giving rise to the menstrual hæmorrhage. The further growth of the venous plexus was also arrested by pressure. The true cause of menstruation on this theory was, then, the emptying of a vascular reservoir with the development of new material. There was thus a successive growth of the endometrium exactly similar to that of the ovarian cortex, and these two parts of the utero-ovarian system were physiologically linked together in the closest possible manner. It was extremely rare to have ovarian disease without preceding or accompanying endometritis, though the latter was not always associated with ovaritis. There were three essentials for normal menstrual hæmorrhage, namely, (1) the complete emptying of the venous reservoir; (2) prompt evacuation of the uterine vessels; (3) no remaining distention of veins. If the process was not completely accomplished the membrane would become thickened when the next cycle of growth occurred, on account of the venous hyperæmia still remaining from the preceding cycle. Consequently there would be a successive development of abnormal tissue, and the result of this would be chronic endometritis of catarrhal, vegetative, or other character, with its pain in the back and hips and other characteristic symptoms dependent on the condition of the ovario-uterine nerves. Many of the symptoms were those common also to pregnancy, such as nausea (which was never met with when the cervix alone was affected), vasomotor derangements, headache, and cerebral disturbances. Such symptoms were also observed in connection with cases of central hysteria where no pelvic lesions could be discovered, but it was probable that in these instances there had been a temporary endometritis present. The following symptoms were considered as pathognomonic signs of endometritis: (1) pain resulting from the introduction of a probe into the uterine cavity; (2) hyperæmia as indicated by the hæmorrhage excited by the passage of the probe, and (3) tenderness of the fundus uteri when pressure was made upon it through the abdominal walls. Dr. Jacobi denied that there was such a thing as ovarian dysmenorrhœa. Whenever there was pain during menstruation in cases with ovaritis it was uterine and not ovarian. The characteristic of pain from ovarian disease was that its maximum intensity was reached during the premenstrual week, and that it was relieved when the flow came on.

One of the serious effects of endometritis was periuterine inflammation, and on account of the tendency for this to occur it was of paramount importance in the treatment that the rhythmic character of the menstrual process should be kept in view. The limits of danger, she believed, were insufficiently defined in the minds of the profession. After the close of the first week after the flow ceased the danger of setting up periuterine inflammation by making applications to the uterine

cavity commenced, and it was therefore unsafe to practice such treatment for two weeks before the beginning of menstruation.

Another important effect of endometritis was the production of uterine flexions. This was due primarily to the softening of the uterine stem in consequence of the inflammatory process. If the latter was confined to the cervix alone, no such result would follow; but if it extended to the cavity of the uterus there was always danger of such accidents. The production of uterine flexion was then illustrated in the case of a girl suffering from chloro-anæmia. There was, first of all, low arterial tension, and after a time, as a result of this, leucorrhœa (due to cervical catarrh). Finally, after some years, perhaps, endometritis ensued; the fact of the extension of the trouble above the cervix being first indicated by the commencement of pelvic pains. Then, and not till then, would flexion of the uterus be noticed, unless it was one of those exceptional cases in which the flexion was congenital. The uterus was enmeshed in a fibro-muscular structure similar in character to its own tissue, and of which, indeed, its parenchyma was only a more condensed portion. Now the characteristic tendency of such fibro-muscular tissue was to contract, and hence when the uterine stem became softened in consequence of the presence of endometritis the contraction of the round ligaments would naturally produce anteflexion. Retroflexion, on the other hand, was a paretic phenomenon, and the essential prerequisite for its occurrence was relaxation of the round ligaments. In retroversion there was relaxation of the utero-sacral ligaments also, and in complete prolapsus there was a total collapse of all the ligaments. A permanent cure for displacements was not to be expected, therefore, from simply holding the uterus in position by means of a pessary, except in very rare instances where the condition has been merely temporary.

The treatment of endometritis naturally resolved itself into three parts. In the first place, whatever would be of service in raising the arterial tension throughout the body, and especially in the pelvis, would do good, and among the agencies recommended were hydro-therapeutics, counter-irritation by means of sinapisms, etc., faradization, general gymnastics, and the health lift. Some such general measures were indispensable in all cases. In the second place, local treatment of the endocervitis existing in connection with the endometritis was advised. The dissipation of the hyperæmia of the cervix might, perhaps, affect the latter condition so favorably that no applications to the cavity of the uterus would be required. For this purpose iodine was often of great service, on account of its stimulating effect upon the pelvic circulation. In many cases, however, it was dangerous on account of this, and, as a general rule, in proportion to the sluggishness of the circulation would it be found efficient. In the third place, if, after a time no effect was produced upon the endometritis by the treatment of the cervix alone, direct local applications were to be made to the cavity of the uterus. The utility of this procedure and the character of the agents to be used for the purpose had excited much violent controversy, and different authorities had expressed widely different opinions. After recapitulating the advantages to be derived from such applications, and the dangers which were liable to result from them, Dr. Jacobi went on to say that it was necessary to define what was to be expected from the treatment before entering upon it.

In regard to the use of astringents she said that it was impossible to expect any benefit from the application of such agents to the uterine vessels while in a state of growth, as indicated by the successive development of neoplasm. This was well illustrated in nævi, where the use of astringents was of no value. An application that was really of service would have the effect of destroying abnormal tissue, modifying the condition of the blood-vessels by reflex influence, and imparting a healthful impulse to the movement of growth, which would moderate its extent at the succeeding menstrual cycle. The time when neoplastic tissue could be most successfully destroyed by such applications was when it was at its lowest point of activity, and that was during the first week following menstruation. As before mentioned, two weeks before the occurrence of menstruation the danger of exciting peri-uterine inflammation commenced, and it was therefore important that the time for such applications should be limited exclusively to the week following the period. Another point of importance to observe was that the effect of one local application must have completely subsided before another one ought to be made. Such applications were always liable to cause a certain amount of irritation, which was analogous to that occasioned by scraping the periosteum in scrofulous subjects. Once in two months in some cases was as often as it was desirable to repeat them. In order to make the application satisfactorily it was sometimes necessary to dilate the canal by means of tents, and this was attended by more danger when ovaritis than when parametritis was present. Every intra-uterine application was to be regarded as a surgical operation which was only to be performed at the house of the patient, who should remain in bed for the rest of the day, and if a tent had been used, for three days afterward. Having expressed a preference, as a rule, for the use of the strong mineral acids, and particularly nitric and chromic acids, for the purpose, Dr. Jacobi stated that the proper effects of the treatment would be observed (1) in the diminution of leucorrhœa, (2) in the relief of the pains in the back and hips, and (3) in the less painful character of the next menstruation. Intra-uterine applications were never to be made unless the patient suffered from some form of dysmenorrhœa. In conclusion, she said that this procedure was confessedly attended with certain disadvantages and dangers, and that the reason why she advocated it was because results could be achieved by this method which were unattainable by any other means.

Dr. B. F. Dawson remarked that the position taken by Dr. Jacobi in regard to so-called ovarian dysmenorrhœa, that the pain was always premenstrual and was relieved when the flow commenced, would seem to be a sound one on theoretical grounds; but at the same time he had undoubtedly seen cases in which no trouble of any kind whatever except ovarian disease could be detected, and yet in which the pain continued throughout the whole menstrual period.

Dr. Paul F. Mundé thought that as a rule in endometritis (which, he agreed with Dr. Jacobi, was due to subinvolution, either menstrual or puerperal), the external os was widely gaping, and that the internal os was also considerably distended. This he regarded as one of the signs of endometritis as well as those which had been mentioned. He considered it of great im-

portance that the treatment should be commenced at as early a period as possible (just as soon as the condition was recognized), since the longer the trouble continued the more difficult it was to cure, if it could be cured at all. When pelvic cellulitis and peritonitis were present, it was necessary to remove the uterine catarrh on which they depended; but, at the same time, it was not to be forgotten that the use of intra-uterine applications was liable to set up additional inflammatory trouble. He could not agree with the author of the paper that parametritis was principally dependent on trouble at the fundus uteri, as his experience had indicated that it was more frequently associated with disease of the cervix, which he believed was on account of the closer lymphatic connection with the latter. The same, he had found, was true in regard to ovaritis, and hence he was always afraid to treat disease of the cervix if the ovaries were affected. Having spoken of erosion of the external os as another sign of chronic endometritis which Dr. Jacobi had omitted to mention, and stated that fundal tenderness (through the abdominal walls) was also an indication of areolar hyperplasia, as well as endometritis, he said that he thought the author's theory of uterine flexions was an ingenious and plausible one. In regard to the treatment of endometritis (which he considered in the majority of cases was merely palliative), he thought the applications must be made from the fundus downward, and not the reverse, since if they were made first to the cervix the discharge from above would be a continual source of fresh irritation. He agreed with Dr. Jacobi that it was the stronger remedies that were of the greatest service, and there was one means that had not been mentioned which he often found of much benefit, particularly in cases attended with menorrhagia, namely, the use of the dull curette. After employing it he applied a caustic to the mucous membrane. He thought it was not necessary to dilate the canal, as a rule, and this was to be especially avoided if there were any parametritis present.

DR. W. GILL WYLIE referred to the not infrequent presence of salpingitis as a complication of endometritis, which rendered it incurable. The influence of specific disease, he thought, was also to be taken into consideration, and this was very apt to be associated with salpingitis. In the treatment he spoke of the advantage of rest. During the acute stage local treatment was more or less dangerous, and he thought it was often best to wait six months, in the meanwhile employing preparatory treatment, which he thought was of great importance. Applications to the vagina were very useful, and for this purpose he preferred tampons of pure glycerine, or of glycerine and alum. He thought that dilatation of the uterine canal was absolutely necessary in a great many cases, and for this purpose he employed Sims's dilator. He had given up the use of tents long ago, except in very rare instances. In making intra-uterine applications it was usually best to place a tube in the cervix first, so that the agent employed would not be rubbed off the applicator before it reached the fundus, the direct medication of which he regarded as a very important point. If it was necessary to use tents he had them prepared with a large percentage of iodoform, so as to render them antiseptic, and he said he also used iodoform in connection with all vaginal tampons.

DR. MARY PUTNAM JACOBI thought that a very tight condition of the internal os was very common. She said she had not referred in her paper to salpingitis and gonorrhœal trouble, because she was speaking only of homologous disease, and not of heterologous, which depended on infection, and was altogether a different matter. The prognosis in endometritis depended a good deal on the nature and general condition of the patient. In those with chlorotic tendency and imperfect development, and in those who from any cause had been reduced to a condition of exhaustion, it was much less favorable; but it was, unfortunately, too often the case that the treatment was exclusively local, instead of being directed to the improvement of the general system as well.

PROCEEDINGS OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.

ALBERT N. BLODGETT, M. D., SECRETARY.

MARCH 12, 1884.

Meeting called to order at eight o'clock. Dr. Edes being absent, on motion of DR. J. W. FARLOW Dr. E. T. Eastman was elected chairman *pro tem.* A summary of the records of the last meeting was given by the Secretary, which was approved.

The first paper of the evening was by DR. G. LIEBMANN, entitled

SPINAL IRRITATION AND NEURASTHENIA.[1]

DR. S. G. WEBBER in opening the discussion said that the difference between neurasthenia and spinal irritation is not so definite as the author states in the paper to which we have listened. The two diseases depend upon similar conditions. The distinctions made in the paper are purely arbitrary. The two affections run into each other. That state or condition which the author calls "false spinal irritation," depending on irritation of the pelvic organs, cannot be too constantly kept in mind. We do not always realize how much disturbance may arise from this cause, not only in women but also in men. Dr. Webber is far from satisfied with the usual explanations of spinal irritation, and does not believe that anæmia or hyperæmia of the cord is a necessary or universal condition. In many cases there may be at times excess and at other times deficiency of blood supply. In most patients it is doubtful if the symptoms depend on disturbances of the circulation. There is probably an exhaustion of the nerve cells, often in the brain, sometimes in the cord or in the sympathetic system. Their reactions are irregular, and disturbances of function and secretion result. Heredity exerts a grave influence in neurasthenia and spinal irritation, and is an important ætiological factor in these diseases. In such cases the parents, frequently one, often both, have not strong and vigorous constitutions. The scenes and influences of childhood are sometimes at fault, and the neurotic condition may be developed where there is no hereditary tendency. Late hours are not beneficial to children, but predispose to the various neuroses. We do not see children romping and playing nowadays as was the habit years ago, but they go to evening parties, sit up late, and eat stimulating food at unseasonable hours. Too warm and ill-ventilated rooms

[1] See page 460 of this number of the JOURNAL.

are also doubtless predisposing factors in the production of nervous diseases. Our school-rooms are often kept at a temperature of 72° F. to 75° F. Children are also sent to school at too early an age, and are thus exposed to unfavorable influences at a perilous period in their nervous development, and frequently become the subjects of neurotic derangements.

Dr. J. J. Putnam said that he did not believe that there was any clinical or pathological advantage in trying to draw a line between neurasthenia and "spinal irritation," so called.

The former term, although vague, is a convenient one, and does not, like the latter, prejudge the pathological diagnosis. Our knowledge of the functions of the spinal cord does not justify us in referring the majority of the symptoms of so-called "spinal irritation" to disease of that organ. On the contrary, the complicated cerebral functions, including those which have to do with the animal and vegetative processes, probably are affected in all the cases of this class, and this affection furnishes their predominating characteristics. It is on these functions that the evil influences transmitted by heredity mainly fall.

At the same time it is not to be denied that the ganglia of the spinal cord and sympathetic may share in the disorder. Dr. Putnam agreed with the reader and with Dr. Webber that the tendency has been to pass slightingly over the nervous symptoms to which diseases of the male genital organs may give rise, although it is true that congenital instability of the central nervous system is usually needed to furnish the material for these symptoms.

Dr. Douglass Graham said he thought we were inclined to be myopic in limiting our observation to reflex neurasthenia arising from irritation of the sexual organs alone, even if this were one of the most frequent causes. Pain or disturbance in any organ, especially below the diaphragm, he said, gave rise to reflex neurasthenia. Indeed, neurasthenia forms the background to the picture of all diseases and injuries whether of an organic or functional nature. The simplest form of neurasthenia is the natural and not unpleasant fatigue which results from an active and satisfactory day's work, from which we recover by food and sleep. After this comes the fatigue from which we do not recuperate as usual, the fatigue of being overworked, or in common parlance "played out," when rest and change are of the first importance. Thirdly, there are the continually wearied, wakeful, nervous business or professional men with numerous and varying ailments who have learned by experience that "the labor they delight in physics pain," and who find more relief in work than in rest. Many physicians, doubtless, find themselves in this class, especially at this time of year. Then there are the neurasthenics who are such because they have no object in life, who are spoiled children with plenty to live on and usually more, who can do what they please and cannot do what they do not please, who take delight in telling of all the eminent medical authorities whose care they have been under without benefit, and who are never happier than when they can be regarded as interesting, by trying some method of treatment that is novel to them, so that they may finally have the satisfaction of saying that it did them no good. A classification of neurasthenia based on causation might be indefinite.

Dr. G. L. Walton considered the brain the chief if not the only sufferer in the cases under consideration. Certainly such symptoms as cramps and pain in the back and loins could arise from the brain as well as from the cord, while the mental symptoms could only arise from the brain. Whether the spinal centres were implicated or not, enough had been said to show the non-existence of a distinct class of cases to be gathered under the term spinal irritation. In this case further division into pseudo-spinal irritation was absurd. He thought that all we could say by way of pathology at present was that there is a large number of nervous patients whose symptoms fall neither under hysteria nor hypochondria, whom we may name neurasthenical, locating the functional disturbance in the central nerve cells. It remained to inquire if the sub-classification proposed would prove of clinical value. The impression conveyed by the paper was that the practitioner had only to ask himself whether the patient before him suffered from neurasthenia, spinal irritation, or pseudo-spinal irritation, and to regulate his treatment accordingly. In point of fact all these cases had to be treated as individuals, one needing rest, another exercise, and so on, any attempt to treat in classes being destined to prove a failure.

Dr. Morton Prince spoke as follows: There is one point which has been raised here on which I wish to say a few words, and that is the question of the cerebral origin of the symptoms of spinal irritation. I cannot agree with Dr. Putnam as to the cerebral origin of these symptoms. This view has lately been advanced with considerable force in an article by Dr. Walton. That some of the symptoms met with in spinal irritation, or neurasthenia (as you may choose to term it), such as vertigo, melancholia, anorexia, pains about the scalp, mental weakness and irritability, and many symptoms distinctly hysterical, are cerebral in their nature every one admits. About such symptoms there is no question. But that there is another larger group of symptoms which are of spinal origin I believe there is also no question. Such symptoms are numbness and pricking in different parts of the body, pains over the spine, neuralgic pains of all kinds. In some cases of nervous prostration the cerebral symptoms may be so prominent as to predominate. Such cases have been denominated *cerebrasthenia* in distinction from others where the cord and nerves are principally implicated.

When a functional nervous disease is met with the symptoms presented are individually such as are caused by organic disease of the same segment, the difference being due not to the essential character of the symptoms, but to the method of grouping, the absence of some symptoms and presence of others, the onset, course, severity, etc. The symptoms met with in functional disease of the cord are such as occur in organic disease of the same part, and the symptoms observed in functional disease of the brain are such as occur in organic disease of the brain. In other words, the symptoms caused by functional or organic changes in a part are conditioned by the physiological functions of the part. For example, we get atrophy with the electrical reaction of degeneration in the muscles of the limbs from organic disease of the anterior cornua of the spinal cord and not from disease of the brain, and conversely we get aphasia from disease of the brain and not from disease of the cord. Now the group of symptoms met with in pure spinal irritation (?) are such as are met with in organic disease of the cord and not of the brain; and therefore there is every reason to believe that their

origin is spinal and not cerebral, and especially is this the case when in severe cases the symptoms are so similar to, nay, almost identical with, those produced by inflammation of the cord and its membranes that it may fairly be questioned whether we have not to do with an organic and not a functional disease. I cannot help thinking that some cases which have been described as spinal irritation are in reality mild forms of inflammation.

I do not mean to say that some of these symptoms may not occur isolatedly in organic brain disease. That may happen with some symptoms, as, for example, anæsthesia and paralysis, which are common to both spinal and cerebral disease. But they do not occur in similar groups, and some symptoms are not present at all. In functional brain disease nearly every kind of symptom may be met with, but here the grouping is different, and it is a question whether some of the symptoms of functional brain disease, as hysteria, may not be dependent upon implication of the cord. In fact this is much more likely than that the fundamental symptoms called spinal irritation are due to cerebral disease.

As this is a practical and important question it may not be out of place here to refer to the argument advanced in the paper I have just mentioned. Pains in the back and sensitiveness over the spine are referred to irritability of the *cerebral* centres, because the centres for *feeling* are in the brain and not in the cord. A similar process of reasoning would as well explain the pains and tenderness complained of in sciatica, spinal meningitis, and myelitis by a disease of the brain.

In regard to the differentiation of spinal irritation from neurasthenia, Dr. Prince was glad to hear Drs. Webber and Putnam express doubts as to whether they could be regarded as distinct diseases. If we examine the descriptions of spinal hyperæmia, anæmia, irritation, and neurasthenia given in the text-books, it would be found impossible to form any clear and definite picture of each as distinct from the others. Erb, to be sure, had described neurasthenia as characterized by being more common in the male sex, while the symptoms exhibited were principally sexual and motor weakness, sensory disturbances being less prominent. Spinal irritation, on the other hand, he had practically limited to females, while the sensory disturbances were very prominent. Ross, in England, had followed Erb's description. In America, on the other hand, the speaker thought that it was the general experience of neurologists that neurasthenia was greatly more common in women, while the group of symptoms included under the name was identical with that described in Germany and England as spinal irritation. It did not seem, then, that there was sufficient grounds for differentiating two diseases.

It is possible that the disease could be occasioned by molecular changes in the spinal cord without having resort to the theories of anæmia or hyperæmia. Sigmund Mayer has made some investigations on the changes which physiologically occurred in normal nerves. His observations were made on the nerves of a large variety of animals and also of men, and showed that the peripheral nerves of vertebrates are not fixed structures, but are continually going through a process of degeneration, followed later by regeneration and a return to the normal condition. The changes observed were similar to those which take place in a nerve which has been divided or otherwise injured. These changes he believes to be constantly taking place, so that in every nerve may be found a number of fibres in this condition.

The thought naturally suggests itself whether these changes may not play some important part in the production of functional nervous diseases. Mayer suggests that this may be the case, and that those neuroses represented by transitory impairment of the sensory and motor functions are due to an increase in the normal number of degenerated fibres, and thinks that these changes are destined to become prominent factors in future neuro-pathology. If these results shall be confirmed by other observers, we have here a means of understanding how disturbances of sensation and motion such as are met with in neurasthenia may be caused by molecular changes alone, and this thought is reenforced by the fact, that while the anatomical changes which are said to occur in normal nerves are similar in kind to those observed in an injured nerve, differing only in degree, so many symptoms met with in spinal irritation (neurasthenia), such as formication, numbness, pain, muscular weakness, etc., are similar in *kind* to those caused by injury to a nerve, though they differ in degree, grouping, mode of onset, and persistency. If similar changes shall also be shown to take place in the central nervous structures, we shall have a complete theoretical picture of anatomical changes which may be at the bottom of neurasthenia.

The idea at present is merely speculative, but is interesting as suggesting a direction for future investigation.

(To be concluded.)

Recent Literature.

The Medical Register for New England. By FRANCIS H. BROWN, A. M., M. D. Boston: Cupples, Upham & Co. 1884.

Perhaps if it were known as the Medical Directory the object of this book would be more easily recognized; but it is very much more than a directory, it is a register not only of the regular physicians of New England, but of all sorts of information more or less remotely connected with the subject of medicine. It contains a list of Associations and Societies: Medical Schools and Kindred Institutions, Hospitals and Dispensaries, Benevolent and Charitable Asociations and Asylums, information in regard to Miscellaneous Matters, beside the Directory and Business Guide. The Directory contains an alphabetical list of the members of each State society, and also a local list in which the physicians of each town are given.

This list of subjects fails, however, to give a just idea of the valuable information which the book contains. The last edition was published in 1880. The labor and time spent in the preparation of the new edition, which contains increased material as well as the changes that have taken place during the four years, must have been enormous, and we trust a generous support at the hands of the profession will show the author that his labor of love is duly appreciated.

— The published report of an English benevolent society says: "Notwithstanding the large amount paid for medicine and medical attendance very few deaths occurred during the year."

Medical and Surgical Journal.

THURSDAY, MAY 15, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

THE MEETING OF THE AMERICAN MEDICAL ASSOCIATION AT WASHINGTON.

THE thirty-fifth annual meeting of the American Medical Association at Washington has been from many points of view a peculiarly successful one. About thirteen hundred delegates were in attendance, and a fair proportion of time was devoted to the transaction of business and to hearing and discussing papers. The work in the Sections was not all of equal merit. Some of the Sections, however, and notably those on the Practice of Medicine and on Obstetrics and Diseases of Women and Children, were prepared for with unusual care, and their programmes offered many interesting titles and strong names. Several of the papers read in these Sections were excellent. Unfortunately, the programmes were out of proportion to the time allowed, and several members who had taken much pains in their preparation, and came a long distance for the purpose, were unable, after all, to read. This was especially the case in the Section on the Practice of Medicine. Such sources of disappointment and dissatisfaction should be avoided if possible. It is, of course, not always easy to accomplish this, and it is quite as undesirable to have to cut short a profitable and animated discussion of a suggestive paper already read as it is to leave unread a paper on another subject. One tendency should certainly be summarily dealt with; we refer to the practice of reading a roll of previously-prepared manuscript, more or less germane to the subject in hand, instead of discussing the views set forth by the reader of the regular paper itself.

The subject of Ethics was not brought prominently forward, except in the address of the President of the Association, Dr. Austin Flint, his remarks being referred to a committee for consideration. As at the last meeting, delegates were required to sign an agreement to support the Code and the laws of the Association. We do not learn that any one felt persecuted, unless it may be some gentlemen in the State of New York. The difficulty about the Code seems to have narrowed itself down to a squabble between New York and the rest of the country. One loyal delegate from New York we thought justly aggrieved at being asked if he had signed with mental reservations, and apparently for no other reason than his coming from that State.

The President's views as to the reforms required by many American medical colleges were evidently not sufficiently advanced to satisfy a large and influential portion of his audience.

The appointment of a committee to invite the International Medical Congress of 1887 to meet in this country was a very suitable step, and we understand the chairman thinks it probable that the proposal will be favorably entertained.

The public collections, the agreeable excursions, and the generous hospitality of the city were thoroughly appreciated by the delegates and their families, and undoubtedly added much, as was to be expected, to the success of the occasion. For further details readers are referred to our Washington letter and to the reports of the meetings.

THE THERAPEUTICS OF EARLY RISING.

THE subject of early rising has a physiological and a therapeutical aspect.

It may be laid down as a general proposition, applicable to the great majority of men, women, and children in health, that the proverb "early to bed, early to rise," etc., embodies sound common sense, and is safe to follow, enabling those who conform to it to perform the greatest amount of work of which they are capable with economy of time, of eyesight, of nervous energy, and of the general health.

The tendency of modern civilization has been to lead people greatly to disregard nature's law (to which the inferior animals generally conform), whereby night is the time for rest, and day is the time for toil. This law is a result of natural selection, as pointed out by one of its great apostles. "An animal so constituted that waste and repair were balanced from moment to moment throughout the twenty-four hours would, other things equal, be overcome by an enemy or competitor that could evolve greater energy during the hours when light facilitates action at the expense of being less energetic during the hours of darkness and concealment."

Early rising is the proper sequel of early retiring, and when recommended as a hygienic rule it is with the presupposition that ample time — which with every individual is a fixed quantity — shall have been devoted to sleep.

The majority of laboring people, in accordance with the necessity in most adults for about eight hours' sleep a day, have wisely chosen the period between nine o'clock in the evening and early morning, and farmers who, retiring in the summer at dark, arise at daybreak, testify to the extraordinary salubrity of the morning air. The atmosphere then is cooler and more invigorating, more heavily charged with oxygen, than later in the day when rarefied by the heat of the sun. There is no time so favorable for exercise, as students well know who are in the habit of taking long walks or practicing gymnastics in the morning before breakfast. An hour spent in exercise at this time of day will fortify a student more than two hours of bodily training at midday, and this season should be chosen for physical rather than for mental exercises.

If sufficiency of sleep be necessary, excess of time

spent in repose is enervating and harmful; it promotes languor of the circulation, and thus induces torpor and congestion of the viscera; it interferes with the energetic performance of the respiratory function, on which the due oxygenation of all the tissues depends; muscular tonicity and nerve nutrition are also enfeebled by prolonging the season of sleep.

From what has been above said it may be inferred that in pathological states characterized by deficient metabolism of nitrogenous waste elements, where, in common parlance, the biliary function is said to be deranged, early rising, with exercise in the open air, will be of powerful therapeutic efficacy. The blood is charged with the products of defective oxidation, the result of over-eating or over-work (or both combined), and all the symptoms of liver indigestion ensue. Here the best hygienic advice is that of old Dr. Abernethy, "An axe, a cord of wood, and five o'clock in the morning!" Under this regimen the "biliousness," with its attendant headaches, malaise, loss of appetite, etc., will often disappear as if by magic. If it is "the early bird" that catches "the worm," it is the early bird that can digest the worm. Dr. Abernethy's advice applies to many cases of simple dyspepsia, which will be more speedily and permanently benefited by early rising than by wine bitters and pepsine; it may also be indicated in gout and diabetes, which are diseases of mal-nutrition.

As for nervous disorders, those characterized by spasm are, as a rule, more amenable to this kind of hygiene than paretic diseases, a recumbent posture increasing spinal reflex activity. Epilepsy and hysteria have both been benefited by the establishment of correct habits of sleep and by early rising, and to a certain class of debilitated young men (with whom every physician has much experience) no counsel is more important than to rise as soon as the first sound sleep is over. As for cases characterized by exhaustion and loss of power (neurasthenia and the paretic diseases of the nervous system), long-continued rest is often the only treatment that does any good. The damaged nervous elements have lost the power of rapid recuperation under sleep, and early rising would, in such patients, be a cruelty if not an impossibility. Reserve force is lacking, and morning weariness is often overpowering. Other persons are neurasthenic from want of a proper hygienic education, and cannot be too much exhorted to curtail the hours devoted to enervating inaction. To such patients the effort, persisted in, of early "springing from the bed of sloth," and engaging in some energetic occupation, is a victory over their infirmity.

In anæmia and chlorosis a "morning air bath" (as Dr. Franklin styles it) is often more beneficial than a course of iron and arsenic.

The victim of insomnia must sometimes, perforce, lie abed in the morning; hours lost in vain attempts to go to sleep may be partially made up by prolonging the season of rest, and subsomnolent states are, as Dr. Crichton Browne observes, the next best thing to sleep. For the great majority, however, of people who are not bedridden a matinal walk is better than medicine.

LEPROSY IN THE HAWAIIAN ISLANDS.

THE report of a recent suit for libel in Honolulu, brought by a Dr. Fitch, one of the Board of Health, against the proprietor of the *Saturday Press*, furnishes information of much interest and importance in relation to the present condition of leprosy in those islands, and explains why the disease still prevails so extensively in spite of the law of segregation. The editor of that journal had published an article exposing "the criminal mismanagement of leprosy in these islands by the Hawaiian Board of Health, of which body Mr. Gibson, the premier, and Dr. Fitch were the officials chiefly responsible."

During the trial Dr. Fitch, who was the principal witness of the prosecution, testified that leprosy is the last stage or form of syphilis, that its period of incubation is twenty-five days, that in most cases it is not contagious, and that in old persons it has passed the contagious period. Several witnesses for the defense testified that he had claimed to be able to cure leprosy, and it appeared that his diploma and professional antecedents were of doubtful character.

Among the physicians called to give evidence for the defense was Dr. Trousseau, a member of the examining board who send lepers to Molokai, who stated that he had been studying the disease in the islands for twenty years, and had sent some seven hundred lepers to the hospital. He believed it to be fully as contagious, if not more so, than syphilis, and that it was contracted by absorption or inoculation, by contact with the abraded portions of a person's body, by the lips in using a pipe, by the mouth in eating poi, or by sexual intercourse. He regarded anything but segregation as dangerous. He had never known an authentic case of cure. The period of incubation in his opinion was probably six or seven years, the proof being that no young children have it, although suckled by leprous mothers, the disease appearing after a lapse of about this number of years.

Dr. Emerson testified that he received his medical education in the Harvard Medical School and in New York. Had practiced in Honolulu between four and five years. Had had charge of the leper settlement at Molokai for the greater part of eighteen months. He believed that the disease was contagious in about the same degree as syphilis and under similar conditions. As a rule Hawaiians lack proper fear of leprosy. With regard to the period of incubation, it was his belief that five years was an average and considerably under the maximum. He had not known of a case of continuous improvement of five years, treated or untreated.

W. M. Gibson, Premier and President of the Board of Health, stated that he had been present with his majesty when lepers were discharged by order of the Board on Dr. Fitch's statement; that some forty or fifty were discharged from the branch leper hospital in one year, and about twenty from the leper settlement since Dr. Fitch's administration. That he had never known of lepers being discharged as cured during the administration of Dr. Emerson. He had al-

lowed an article entitled Lepers Cured and Discharged to appear in the paper of which he is proprietor.

Several discharged lepers were then introduced and found to be in an active state of disease.

The following extracts from Mr. Dole's address to the jury reflects the feelings of a portion of the community there concerning the disease, and are commended to the attention of our own National Board of Health: —

"This is a case in which the most important question before the Hawaiian nation is being tried on its merits. The community have from time to time become alarmed on the question of leprosy, and then the rush of business and other interests have driven it aside, and society with its pleasures and its cares has allowed itself to go to sleep in the face of the greatest danger that has ever threatened it. It is well that society should be awakened from this sleep, and I believe that this case of libel you have been so long considering, in which Dr. Fitch is the prosecuting witness and Mr. Thrum the defendant, will accomplish this.

"Leprosy is the worst known disease of the present and historic times. It has successfully defied medical skill. Physicians have not been able to say whence it comes or to explain its laws. It has always and everywhere been found to be incurable. It attacks all races and all classes; no rank in life is safe, adults and children are alike exposed to its ravages. Medical skill can make no limit, no assurance can be given from the lessons of experience against this most terrible, most loathsome, and most hopeless of all human diseases. But Dr. Fitch has come, like a new Columbus breaking an egg, to tell the people of this nation that leprosy is identical with syphilis, a disease which is remarkably amenable to medical treatment, and is undoubtedly curable. It is for discussing this theory of Dr. Fitch and criticising his statements and methods in applying it, that the defendant is charged with the crime of libel. The subject is one of vast interest to the whole community. Nearly all of the physicians of this country have been studying the disease of leprosy for years; they have not hesitated to expose themselves to its contagion, have patiently investigated its nature, trying to discover some clew that might lead them to some method of treatment which would conquer a disease which has hitherto been found unconquerable. All the physicians here agree, with one exception, and that one exception is Dr. Fitch, that leprosy is altogether distinct from syphilis. All the great medical authorities over the world, without exception, support this view. Upon this question depends the moral, social, and commercial future of the Hawaiian Islands. . . .

"Now the existing management of this matter of leprosy is more important to this community than any other question. It goes to the pocket of every taxpayer. It is a menace to property, to society, to health and life. It is the great public question, and Dr. Fitch is its principal exponent. The legislature and the government have given him great powers. He is the chief executive officer in the treatment of leprosy. He is an agent of the Board of Health, with the law and the police at his back. He has more power for good or ill than any other officer in the kingdom; and though his rank may be lower and his salary less than that of other officers, he holds to-day the most important office under the Hawaiian government, for on the proper exercise of the authority of his office depends the health, the wealth, and the future of the realm; and if he may not be held to a strict accountability, if his methods and professional conduct be not fair subjects of newspaper inquiry and condemnation, then there is no such thing as freedom of the press and free speech in the kingdom. We all know something about leprosy. . . . Life to the leper is worthless, and worse than worthless. He is loathsome to others, and most loathsome of all to himself. In the Middle Ages leprosy extensively prevailed, and segregation and nothing else has driven it into the corners of Europe. How is it here? I tell you, gentlemen, the government is playing with this disease. *When you see the king and the Board of Health, all laymen, going on a kind of picnic party to the Kakaako Hospital, taking with them one — only one — physician out of the three medical inspectors of lepers, examining the patients, having them stripped, and, upon the advice of that one physician with his unsupported theories, turning nine of them loose upon the community, and then writing the affair up in a newspaper,* I say it is worse than child's play. And they dare to do this when every medical man in the kingdom, except one, says that such action is dangerous to the public at large, — and that one is Dr. Fitch, the prosecuting witness in this case. . . . We have had medical testimony that leprosy is seen daily on our streets, is found in public places of resort, and among government employees. It is the clearly defined duty of Dr. Fitch to carry out the law of segregation. How has he done it? We find him with his two theories, that leprosy and syphilis are identical, and that leprosy in certain stages is not contagious, or is not contagious at all, as he says in his printed statements. If he confined his theories to private practice we might have less ground for noticing them. But to experiment with his theories at the risk of the whole community, and in defiance alike of medical testimony and public opinion, is an outrage. He admits that Mr. Sumner was discharged upon his recommendation. It was said that Sumner was to be isolated at a private house at Fisherman's Point. But he was not isolated at that place. He remained there a few days, and removed to a house in the heart of the city, near the Hawaiian Hotel; has been to Waikiki; is free, in fact, to go where he likes, and to associate with whom he likes. And there is the unfortunate young lady who, I believe, is a fine school teacher, who has been treated by Fitch for leprosy for more than a year. She has been allowed to carry on a large school of little children for all this time, children who have not the knowledge and discretion of adults in regard to this disease. Is not this almost like murder?"

In his charge to the jury the judge said that —

"The importance of the office held by the prosecuting witness could not be overestimated. If, by any means, these islands should become a plague spot, the effect would be more important upon the future of the nation than the withdrawal of the reciprocity treaty. If the medical man in charge of all those supposed to be afflicted with leprosy should assert and believe that leprosy is not contagious, and succeed in producing a general acquiescence in this belief, the public fears would be lulled, and persons be less likely to be careful in keeping themselves from contagion. The injury which such a course of conduct might entail is untold. And the *Saturday Press* could not sustain its character as a leader or as an exponent of public opinion, or a guardian of the welfare of the country, if it did not expose the falsity of such an opinion, — that is, if leprosy is in fact contagious. So, also, if the medical superintendent and the agent of the health, who has by law almost unlimited powers, shall by his published reports to the legislature, or by his other printed articles or spoken words, induce a general belief that leprosy and syphilis are identical, the result would be that those who are living pure and moral lives would become careless as to the exposure of themselves or their children by mere contact with lepers, believing sexual intercourse, by which syphilis is commonly taken, to be the only way in which they could take leprosy, and keeping themselves free from that. So, if Dr. Fitch should persuade people generally that leprosy is curable, people would become indifferent, and say: 'I have the means of employing a physician; it matters not if I take leprosy. I can be cured.' It has been often stated that among people where leprosy is less feared it spreads with greater rapidity than where it is more feared. Now, you have heard the testimony of all the other physicians, except Dr. Fitch, and quoting from medical authorities all over the world, that leprosy is not identical with syphilis, that it is incurable, and that it is in a certain sense contagious; and if they have proved this to your satisfaction the defendant was justified in what he said of Dr. Fitch. Dr. Fitch has said that he believes in a policy of segregation of lepers. If he allows lepers to be discharged who, by the weight of testimony, are not cured, would this be adhering to a policy of segregation?"

The jury brought in a verdict of not guilty.

MEDICAL NOTES.

— The remains of the late Dr. Samuel D. Gross were cremated at Washington, Pa. They were brought back to Philadelphia under the escort of the family and friends of the distinguished physician. The ashes weighed about seven pounds, were hermetically sealed in a tin box, and placed in the coffin in which the body was carried to Washington. On reaching Philadelphia the coffin was removed to the late residence of Dr. Gross, and subsequently the ashes were in-

closed in a marble urn about three feet high, unornamented and without inscription, and placed beside the coffin of Dr. Gross's late wife in the family vault at Woodland cemetery. Rev. Dr. Charles Currie read the Episcopal burial service at the cemetery.

— Mr. Knowsley Thornton recently removed a cystic spleen by abdominal section (median incision) at the Samaritan Hospital, London. The patient was a single girl, aged nineteen, and the tumor had been growing slowly for two years. Latterly it had increased much more rapidly, and caused much pain. The reports up to the end of the first week show that the patient was progressing quite satisfactorily. During the tying of the pedicle the patient suffered severely from shock, and for some minutes her life was in great danger; but she revived immediately, the tumor was cut away, and the drag taken off the pedicle. The specimen will be shown, and the further progress of the case reported, at the Pathological Society.

— In the recent pedestrian match in New York the strain on the bodies of the leading contestants after the first three days of the walk is described as being intense. Even allowing for possible inaccuracies in the description of the newspaper reporters, one is led to believe, in view of the record of the work done, that the picture drawn is not greatly exaggerated. Speaking of the man who won the race, one of the Brooklyn papers says: "His eyes were sluggish, bloodshot, and heavy, and encompassed by huge purple circles. His cheeks had so sunk in that the contour of the teeth could almost have been seen through them, and every movement was an illustration of acute agony. He swung his arms painfully, his head dropped on his chest, his shoulder blades stuck out sharply from his attenuated body, his legs dragged lamely one after the other, and the muscles of his neck twitched nervously with every step. He dragged himself steadfastly ahead, never turning his eyes to the right or left, until he came to the scorer's stand, when he painfully and laboriously turned his face toward the figures to see that they were correctly given." The change in the Englishman who held the second place is described as even more pronounced and pitiable.

— The medical world is represented in the little volume entitled *English as She is Spoke*, by the following new rendering of an old story, which, though it may leave something to be desired in elegance of diction, is yet admirable in its philosophy: "A physician eighty years of age had enjoyed of a health unalterable. Theirs friends did him of its compliments every day: Mister Doctor, say they to him, you are an admirable man. What you make then for you to bear you as well? I shall tell you it, gentlemen, he was answered them, and I exhort you in same time at to follow my example. I live of the product of my ordering without take any remedy who I command to my sicks."

— To the Pathological Society of London (March 18, 1884) Mr. Roger Williams showed photographs of a boy, in whom the femora were absent. No trace of the femur or patella could be found on careful examination on either side; a bony mass in the groin, and apparently articulating with the pelvis, was ascertained to be the head of the tibia somewhat altered. Mr. John Wood, discussing the case, said that about twenty years ago a man who went by the name of the man-monkey was well known in London; the femora were absent, but he was exceedingly agile, and this, combined with the fact that his hands reached to the ground, had earned him his sobriquet. He thought that one moral might be drawn from such cases, and that was how exceedingly useful one section of a limb might be; it was, he thought, an argument in favor of the operation of excision.

— The following remarkable cases of longevity in husband and wife, at Cleveland, Yorkshire, England, are given by a correspondent of the *Lancet*. James Miller died lately of senile decay. He was ninety-five years old, and was in good health until a few days before his death. He smoked to the last. He wanted his bed removed just before he died, and his wife, Mrs. Miller, who had "an advantage," as will be seen, in point of seniority, and would at the same time appear to have had considerable "force" of character, although she was ill at the same time, remarked, "Ay, he was always first and foremost all his life in everything, and now he wants to be so in death." Mrs. Miller did not long survive her husband, but died on March 17th last of senile decay. She was returned as one hundred and four years of age, and her doctor thinks she might have been living yet had she not refused taking medicine. She had no movement of the bowels for three weeks before her death, and refused the doctor's help. A short time before her husband was taken ill Mrs. Miller wanted him to go to Hinderwell, a good stiff walk. He said he was not able to go; Mrs. Miller replied, "It was nothing but idleness of him." Mrs. Miller, like her husband, was a lover of the "weed," and enjoyed a smoke up to time of her death.

NEW YORK.

— Dr. A. Randolph Mott, resident physician at the Riverside Hospital, Blackwell's Island, died May 6th, of typhus contracted two weeks previously in the discharge of his duties at that institution. He was twenty-six years old, and was born at Leesburg, Va., where his father is a prominent physician. In 1878 he was graduated from the University of Virginia and came to New York, where he obtained an appointment to the medical service of the workhouse on Blackwell's Island. From there he went to the Randall's Island Infant Hospital and Hart's Island Hospital, also under charge of the Department of Charities and Correction, and in 1881 was appointed to the Riverside Hospital, where he remained up to the time of his death; at the same time holding a position in connection with the chair of gynæcology at the New York Polyclinic. The Board of Health has passed suitable resolutions in reference to his untimely decease and the loss of his efficient services.

— A death certificate was filed last week at the bureau of records of vital statistics in Brooklyn, stating that Luke Walker had died in that city at the age of one hundred and one years. He was born in Ireland in May, 1783, and fought under Bolivar for the

independence of Venezuela in 1818. His father is said to have lived to be one hundred and one, his grandfather to be one hundred and two, and his grandmother to be one hundred and ten.

Correspondence.

LETTER FROM WASHINGTON.

WASHINGTON, *May* 10, 1884.

MR. EDITOR, — The thirty-fifth annual session of the American Medical Association has been participated in by nearly 1300 members (registered), is now over, and the vast body dispersed. The meeting was characterized by good temper, earnestness, and an amount of material for work in the Sections which it was impossible to dispose of. The general tone and character of those in attendance was of the best type, and it was a subject of general remark that the appearance of the delegates generally was that of fairly prosperous city men, although here and there were still evidences of very primitive manners, especially at some of the receptions, at one of which two gentlemen? (God save the mark!) spent a large portion of their time in the supper room with their hats on.

The meetings were held in the Congregational Church, which is in the centre of the business portion of the city, and near to the various branches of the street railroad. The church was kept constantly filled, and the acoustics were bad, that is, for some voices. Dr. Flint in reading his address as President could be heard by but very few. The place of registration was, unfortunately, in the main hall, through which every one had to pass to get at the general session, while opposite to those engaged in this duty was a man selling tickets for an excursion to Mount Vernon who kept constantly calling out, "Secure your tickets for Mount Vernon!" About four hundred availed themselves of this opportunity on the last day of the session. The janitor of the church was also busying himself by hanging up placards of "Please do not smoke in this church," and exerting his personal influence to the same effect, which was resented as an impertinence by some, quietly ignored by others, while the good-natured strolled out to the front steps with their cigars. Among the delegates there was quite a sprinkling of women, and the galleries were fairly filled with interested spectators; disgusted, however, on one occasion when the roll-call of the 1200 was ordered and proceeded with, which being so much like many of the proceedings of Congress, they left without ceremony.

The Sections were all well attended, and it spoke very well for the earnestness of the delegates to see this large attendance in a city which, especially at this time, presents so many attractions to the stranger. They also had the weather in their favor, for although it was warm the sky kept overcast, with fresh breezes. The Masonic Temple was set aside for the exhibit of drugs, books, and instruments. It was well filled and tastefully arranged. Men would walk in quietly and soberly to come out with their pockets bulging in the most significant manner, and with their arms filled with bundles. Here you got a cup of hot phosphatized cocoa; there a glass of Hoff's malt extract, in one corner the American preparation, and at the opposite end of the room the German imported article; in another place milk was digested for you after the most approved plan, and you took a glass of that. In other words, one found there a concentration of the book and drug fiends who come into your office with that little black bag, and that "hope-I-don't-intrude" air, to just leave you a little sample of their goods. Talk! Well all you could do was to stand still quietly and look hopelessly at the other end of the room until there was an end to the description, and another victim was secured. Yet the men would go there; almost all went. At the close of the exhibit Dr. D. C. Patterson, who had charge of caring for the exhibitors, was presented by them in a neat little speech with several handsome pieces of silver, and he certainly deserved it for the labor involved.

It was expected that the question of the Code might crop out at this meeting, but there was little said regarding it. The blanks signed by those registering were of the same character with those used in Cleveland last year, and if there were any protests they were not loud enough to excite comment. New York was well represented by some of her best men, L. A. Sayre, Isaac E. Taylor, J. C. Dalton, Flint, Jr., Janeway, C. L. Dana, Gouley, and a number of others, and the impression seemed to be that their new Society organizations would enable them to be independent of their erring brothers, so far as their affiliation with the Association was concerned, and that these might depart in peace. There was very little temper shown about the matter, and the idea was expressed that a large number would see the folly of their ways and come back into the fold. On the last day the committee to whom proposed changes in the Code had been referred made a verbal report, that in view of the departure of so many members it had been decided not to recommend any changes, but a committee was appointed to make such an explanatory declaration of the Code as might be deemed necessary. This was thought advisable, owing to the misrepresentations of certain provisions.

When the question regarding certain resolutions bearing upon the manner in which medical colleges were conducted, and upon medical education, was considered, for a time there bid fair to be a lively discussion, and Dr. Henry, of New York, made some forcible remarks with considerable warmth, but the discussion did not proceed very far, and was closed by the adoption of a resolution offered by Dr. Benjamin, of Maryland, urging upon all medical colleges to require a preliminary education, a three years' course, a register of attendance, and practical demonstrations of diagnostic skill.

The question upon the continuance of the journal of the Association, and the mode of conducting it, caused, as may well be imagined, considerable interest. A great deal of dissatisfaction was expressed as to its general management, which culminated in a printed circular issued by Dr. Packard, who was Secretary of the Board of Trustees, and an attempt was made to transfer the place of publication and editorial management to Washington, Philadelphia, or New York. The friends of the *Journal* as upon its present basis took the ground — and it would seem with reason — that Dr. Packard should have brought forward his objections within the body of trustees, to be discussed there rather than to go forth as his printed circular did; that while there was a desire to meet the best interests of the Association no positive, feasible plan

had been proposed, and no assurances given of any special individuals suitable to take charge of the *Journal*. Dr. Davis resigned his position as editor, but his resignation was not accepted by the trustees, and he was induced to continue the management of the *Journal* for one year longer only, so that it is hoped that by the next meeting of the Association some definite plan for his successor will be determined upon.

The report of the Board of Trustees showed that 3800 copies had been issued, and that after the payment of all possible expenses incurred, including salaries, etc., there would remain in the treasury $500, so that the Association would begin its year from July, 1884, with the whole of the income from the present meeting as a financial basis. Dr. Packard, from the Board of Trustees, read his minority report, embodying what has already been stated, and exciting considerable discussion, during which some rather amusing scenes occurred. A rather small and excitable member upon the platform jumped up to second the call for the ayes and noes, with the remark that he had done so the day before in connection with some other point, but Dr. Sayre had sat upon him and squelched him, when a ponderous member from the other side of the platform hoped Dr. Sayre would sit down again. The ayes and noes, by a vote of 191 to 74, laid the minority report upon the table.

The report of the librarian showed that the library has grown to 6000 volumes. This report should receive more consideration than has heretofore been given to it. With the publication of the *Journal*, exchanges are increasing to a marked degree, and it is time that the library should be utilized in some way. It has outgrown its quarters in the Smithsonian Institution, and if some provision is not made for its proper care it might as well be done away with. The librarian, Dr. Kleinschmidt, states that he has numerous calls for books from all over the country, and as yet has lost none by sending them by express to members.

On the last day of the session a number of resolutions were offered, among which was one by Dr. Gihon, that the Association erect a statue to Rush in Washington. There was a great deal of force in his remarks, but there was no discussion of them. Some one suggested that Simms and Gross, as national representatives of medical science in this country, should be similarly honored.

Dr. Von Klein, of Ohio, offered a resolution to abolish the opening of the sessions with prayer, as the body was composed of so many infidels, free thinkers, materialists, etc., but this was instantly laid on the table. And so, with a number of important motions and resolutions, which will of course be fully reported in your pages, the American Medical Association closed its sessions to meet next year in New Orleans, with Dr. H. F. Campbell, of Georgia, as its president.

The entertainments which took place in the evening were varied and enjoyable. The hospitals generally were not thrown open, with the exception of the Government Hospital for the Insane, upon the invitation of the superintendent, Dr. W. W. Godding, and the Columbia Hospital for women, upon the invitation of Dr. P. J. Murphy, the surgeon in charge, who prepared a lunch there for the use of the Obstetric Section each day of its meeting. Dinners and lunches at the houses of physicians were largely attended. Of the special entertainments the President's reception was the most extensive. As is the rule, there were no refreshments offered, but the whole house, up stairs and down, with the conservatory, was thronged with people, too much thronged for comfort, some ladies being overcome with the crowd and the heat. One very bad feature was the fact that the Marine Band was stationed in the hall-way and gave blast after blast through its brass instruments right into the ears of the packed and jammed crowd of visitors. The President had quite a party of people about him, supposed to be assisting him to receive, but apparently looking on with curiosity at the crowd; to step out of the ranks and into this little party for a few moments and watch the ushers leading people by was quite amusing. The new Siamese embassy was there in full court regalia.

On the second day there was a reception by the profession of Washington in a large hall, with music and dancing, and with abundant refreshments. This was very enjoyable, but it was noticed that there was a marked lack of ladies of the families of the receiving physicians. The few who were there made themselves very agreeable.

On the third day the Corcoran Art Gallery was illuminated, and the venerable W. W. Corcoran, now eighty-four years of age, received the guests with his usual affability and cordiality.

On the fourth day the Surgeon-Generals of the United States Army and United States Navy, with their respective staffs in full uniform, received at the Army Medical Museum, and the President of the Senate and Speaker of the House of Representatives received at the Capitol. There were also receptions at the private houses of Mr. Leiter, of Chicago, who occupies Mr. Blaine's house, the Commissioner of Agriculture Dr. Loring, Mr. Hildrup, and Chief Justice Waite.

Miscellany.

IMPORTATION OF RAGS FROM EGYPT.

THE Marine Hospital Service, through the Treasury Department at Washington, issues the following circular to Collectors of Customs and others whom it may concern: —

The following letter to this Department from the Secretary of State, dated April 16, 1884, is published for your information and guidance, and, until further notice, rags from infected ports will not be permitted to land except under the provisions contained therein: —

"I have the honor to say, in connection with previous correspondence in relation to the proper disinfection of rags imported into the United States from Egypt, that the Department has, upon careful and mature consideration of the subject commensurate with the interests involved, decided upon the following methods of disinfection, either of which will be satisfactory to the health authorities of New York City, New Haven, and Boston, who have been consulted in respect to the matter, namely:

"(1.) Boiling in water for two hours under a pressure of fifty pounds per square inch;

"(2.) Boiling in water for four hours without pressure; and

"(3.) Subjection to the action of confined sulphurous-acid gas for six hours, burning one and a half to two pounds of roll brimstone in each 1000 cubic feet of space, with the rags well scattered upon racks,

"An inspector has been designated, who will have immediate supervision, under the Consul-General, of the process of disinfection, will be required to give the subject his earnest personal attention, and furnish a proper certificate. This certificate will show the following facts: —

"(1.) His name;

"(2.) The name of the consignee in the United States;

"(3.) The place where the rags were disinfected; and

"(4.) The process of disinfection, which must be one of the processes hereinbefore described.

"After that the Consul-General is to authenticate the certifi-

cate given by the inspector. This process is to be observed in the case of every bale of rags, which is to be also marked "Thoroughly inspected," with the name of the inspector.

"The Consul-General at Cairo has been told that, although he should not refuse to certify invoices even when lacking the inspector's certificate, he must give notice to all shippers of rags that these goods will not be permitted to enter the United States unless accompanied by such certificate."

REPORTED MORTALITY FOR THE WEEK ENDING MAY 3, 1884.

Deaths reported 2526 (no reports from St. Louis, Buffalo, District of Columbia, Milwaukee, and Providence): under five years of age, 895; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 428, consumption 381, lung diseases 291, diphtheria and croup 100, scarlet fever 59, diarrhœal diseases 59, measles 49, typhoid fever 42, small-pox 27, malarial fevers 27, whooping-cough 26, cerebro-spinal meningitis 15, erysipelas 12, puerperal fever 12. From *measles*, New York 14, New Orleans 13, Baltimore 11, Chicago and Cincinnati four each, Brooklyn two, Philadelphia one. From *typhoid fever*, Philadelphia 16, New York and Chicago five each, Brooklyn and Baltimore four each, Cincinnati three, Boston, New Orleans, Pittsburg, Charleston, and Lawrence one each. From *small-pox*, New Orleans 21, Nashville three, Philadelphia, Boston, and Pittsburg one each. From *malarial fevers*, Brooklyn seven, New York and New Orleans six each, Baltimore four, Chicago three, Cincinnati one. From *whooping-cough*, New York 11, Chicago and Baltimore four each, Brooklyn three, New Orleans two, Philadelphia and Boston one each. From *cerebro-spinal meningitis*, New York and Chicago three each, Cincinnati and Nashville two each, Philadelphia, Boston, New Orleans, Lowell, and Fitchburg one each. From *erysipelas*, New York five, Brooklyn two, New Orleans, Nashville, Charleston, and Gloucester one each. From *puerperal fever*, Chicago four, Brooklyn three, New York, Philadelphia, Baltimore, New Orleans, and Lowell one each.

Cincinnati reports one case of small-pox; scarlet fever 53, diphtheria 25, and typhoid fever six in Boston.

In 102 cities and towns of Massachusetts, with an estimated population of 1,468,570 (estimated population of the State 1,955,104), the total death-rate for the week was 13.67 against 15.63 and 16.60 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending April 19th, the death-rate was 22.5. Deaths reported 3773: acute diseases of respiratory organs (London) 318, whooping-cough 189, measles 159, scarlet fever 88, diarrhœa 37, fever 40, diphtheria 24, small-pox (London 11, Liverpool and Newcastle two each, Wolverhampton and Sheffield one each) 17. The death-rates ranged from 13.1 in Derby to 28.7 in Bolton; Leicester 16.1; Birmingham 20.2; Birkenhead 20.7; Newcastle-on-Tyne 21; London 21.4; Sunderland 21.6; Sheffield 23.6; Liverpool 25.5; Nottingham 26.2; Leeds 28.4; Wolverhampton 28.6; Manchester 28.7. In Edinburgh 21.4; Glasgow 25.3; Dublin 28.7.

For the week ending April 19th, in the Swiss towns, there were 48 deaths from consumption, lung diseases 21, diphtheria and croup 13, typhoid fever 13, diarrhœal diseases eight, whooping-cough four, scarlet fever three, measles two, erysipelas one. The death-rates were, at Geneva 14.3; Zurich 11.8; Basle 24.8; Berne 33.3.

The meteorological record for the week ending May 3d, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps: —

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM MAY 3, 1884, TO MAY 9, 1884.

WEBSTER, WARREN, major and surgeon. Granted leave of absence for six months from April 29, 1884, on account of sickness. Paragraph 5, S. O. 103, A. G. O., May 3, 1884.

STERNBERG, GEORGE M., major and surgeon. Now at Governor's Island, New York Harbor, ordered to repair to this city (Washington, D. C.) to represent the Medical Department of the Army at the annual meeting of the American Medical Association, to meet on May 5, 1884, and on adjournment of the Association to return to Governor's Island. Paragraph 2, S. O. 103, A. G. O., May 3, 1884.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING MAY 10, 1884.

GRAVATT, C. W., passed assistant surgeon, detached from Naval Hospital, Chelsea, and ordered to U. S. S. Michigan.

HARMON, G. E. H., passed assistant surgeon, detached from the Michigan and granted leave of absence.

EDGAR, T. M., assistant surgeon, ordered for examination preliminary to promotion.

INSPECTOR OF MILK AND VINEGAR.

DR. B. F. DAVENPORT, having been appointed Inspector of Milk and Vinegar for the City of Boston, will be pleased to receive and report upon all samples sold in this city which may be sent in to him at the office, which during the month of May will continue at 30 Pemberton Square, but after that will be in the Old Franklin School Building, 1151 Washington Street, near the corner of Dover Street.

CORRECTION.

THE paper read before the New York County Medical Association on Scarlatina, referred to in the JOURNAL of May 8th, was by Dr. Charles A. Leale.

THE BOWDOIN MEDICAL ALUMNI ASSOCIATION will hold its first general meeting in Brunswick on the 28th of May, the day of the graduating exercises. There will be a dinner and other festivities. The residences of many of the alumni are unknown, and every graduate of the Medical School of Maine who has not received notification of this meeting is requested to send his address to the Secretary of the Association, Dr. C. D. Smith, Portland, immediately.

THE NAVY MEDICAL CORPS. — There are at present twelve vacancies in the Navy Medical Corps. A Board for the examination of candidates for admission into the Corps is now in session at Philadelphia.

SUFFOLK DISTRICT MEDICAL SOCIETY. ADJOURNED SPECIAL MEETING. — *Section for Clinical Medicine, Pathology, and Hygiene.* The adjourned special meeting for the continuation of the discussion upon Sewage Systems will be held at 19 Boylston Place, on Wednesday, May 21st, at 7.45 o'clock. Dr. Faxon, of Quincy, Prof. William R. Nichols and Prof William T. Sedgwick, of the Massachusetts Institute of Technology, Henry M. Wightman, Esq., City Engineer of Boston, Desmond Fitzgerald, C. E., Superintendent Western Division Boston Water Works, Edward S. Philbrick, C. E., Eliot C. Clarke, C. E., and others are expected to be present.

ROBERT T. EDES, M. D., *Chairman.*
ALBERT N. BLODGETT, M. D., *Secretary.*

BOOKS AND PAMPHLETS RECEIVED. — Wharton and Stillé's Medical Jurisprudence. Fourth Edition. Edited by Robert Amory, A. B., M. D., and Edward S. Wood, A. M., M. D. Vol. II. Philadelphia: Kay & Brothers. 1884.

Address.

EXTRACTS FROM THE ADDRESS AT THE ANNUAL MEETING OF THE PENNSYLVANIA STATE MEDICAL SOCIETY.

BY HENRY H. SMITH, A. M., M. D. U. P., PRESIDENT.

MEMBERS OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA, AND LADIES AND GENTLEMEN, — The recurrence of the period when delegates from all our County Medical Societies assemble to interchange professional opinions and renew or form the fraternal ties of a distinguished brotherhood, has again brought us together on this the thirty-fifth annual session of the Medical Society of the State of Pennsylvania.

Welcomed as you have been by our Committee of Arrangements on behalf of the Philadelphia County Medical Society, honored by the presence of the Governor of the Commonwealth, and coming among those who have been the preceptors of many of you, in our well-known medical schools, you hardly need the greeting I tender you this evening, on behalf of our citizens here assembled, in recognition of your presence in Philadelphia.

Chosen to preside over your deliberations, I highly appreciate the unsought honor conferred by your choice, and have entered on the performance of the duties this honor entails with a consciousness that I am dependent on your kind assistance for the proper execution of the functions of the chair.

The By-laws of our Society make it incumbent on your President to deliver a public address, and in the performance of this duty I ask your consideration of a theme with which you are all doubtless more or less familiar, but which now and evermore must be the subject illustrated in these annual assemblies.

This theme I would formulate as —

THE IMPORTANCE AND USEFULNESS OF SCIENTIFIC MEDICAL ORGANIZATIONS TO OUR PROFESSION AND THE PUBLIC.

In order correctly to comprehend the objects obtainable by such organizations it may be useful —

(1.) To note their origin and elementary formation, as described in history.

(2.) Show in what manner our annual meetings are useful to the profession and the public.

(3.) Allude to the reciprocal obligations of the public to the profession.

A *society* has been defined as "an association of individuals voluntarily created for the promotion of knowledge, industry, or virtue, and of planning or creating orders for these purposes." It is especially constituted for the *extension* of knowledge and the general good of the community in which it exists.

The creation of societies is due to comparatively modern periods in the history of mankind, and is evidence of the progress of civilization and literary culture, Alcuin, about 781, under the patronage of the Emperor Charlemagne, being, it is said, the first who attempted to organize one.

The earliest literary society was called an academy, and derived its name from *Academus*, the original owner of the grove in the suburbs of Athens where Plato and his followers held their philosophical meetings.

Cicero also named his villa near Puzzuoli an academy, and is said to have there written his Academical Questions and his book De Natura Deorum. Subsequently the term academy signified "a society of learned men established for the improvement of art or science," as in the Royal Academy of Science in Paris, and our own Academy of Natural Sciences in Philadelphia.

A medical academy or society, designated as that of the "Naturæ Curiosi," existed at an early period in Germany; another was founded at Palermo in 1645; and another met weekly at Venice in 1701.

The Academy de Naturæ Curiosi, or the Leopoldine Academy, was founded by Bauschius, a physician, in 1652. He extended an invitation to all physicians to communicate their extraordinary cases, which, in 1684, were published as a volume of observations under the title of Ephemerides, a title in existence in a journal of the present day.

The most enlarged idea of a literary and scientific society is, however, believed to have originated with Sir Francis Bacon, in England, "who recommended to James the First the institution of societies of learned men, who should give to the public from time to time a regular account of their researches and discoveries, and thus unite the *world* into one great republic of letters, which, though consisting of many detached states, should yet hold a strict union, and preserve a mutual relation to each other in everything that regarded the common interest." In his New Atlanta he delineated a philosophical society which Cowley is said to have presented to Charles the Second of England for the charter of the Royal Society of London, and it may interest some to know that Dr. William Harvey, the discoverer of the circulation of the blood, was, in 1628, physician to Lord Chancellor Francis Bacon,[1] and doubtless participated in the planning of this society.

History has thus demonstrated the utility of such organizations, and that many improvements of a public character have been due to the united labor and intelligence of men interested in one grand pursuit.

The charter of the Royal Society of London was granted in 1662, that of Christian Knowledge in 1698, and that of the British Medical Association in 1832.

The New Jersey Medical Society appears to have been the first medical society organized in this country, it being regularly constituted by the voluntary association of a number of the Practitioners of Physic and Surgery of East New Jersey, at New Brunswick, on July 23, 1766, "for their mutual improvement, the advancement of the profession, and the promotion of the public good." [2]

The American Academy of Sciences was established in 1780, by the Council and House of Representatives of Massachusetts, "for encouraging medical and philosophical discoveries, and whatever tended to advance the interests, honor, and dignity of a free, independent, and virtuous people." [3]

The organization in 1847 of the American Medical Association, of which our State Society is an integral portion, is precisely that which Lord Bacon esteemed so advantageous to the general welfare, it being, in fact, a great republic of medicine in which individual State societies are united in a common interest, namely, the preventing, curing, or alleviating the "ills that flesh is heir to."

In the association of individuals that thus formed

[1] Encyclopedia Britannica, etc.
[2] Narrative of the Rise and Establishment of the New Jersey Medical Society. Transactions from 1766 to 1859.
[3] Dobson's Encyclopedia.

societies it soon became apparent that some laws or rules of action applicable to each and every member must be adopted, in order to regulate intercourse and restrict irregular or individual opposition to the interests of the Society, and that in these laws, as in those of all communities, the most important portion would be "the penal or vindicatory clause," it being useless to say, do this or avoid that, unless the law also declared what would be the penalty or consequence of non-compliance. Ethics, or the law of manners, collected in a paper-book, termed Codex or Code, was thus adopted at an early period in the history of all societies, and the Code of Ethics of the American Medical Association is but another illustration "that history repeats itself."

In this Code the vindicatory or penal clause is found in the By-laws, and as the Code is accepted by each society, it is applicable to every one who is elected to membership in a State or County society. In the ninth by-law of the American Medical Association the rule explicitly states that "no State, local society, or other organized institution shall be entitled to representation in the Association that has not adopted this Code of Ethics, or that has intentionally violated or disregarded any article or clause of the same." [1] Consequently, the penalty of violation is exclusion and loss of membership, which also implies non-intercourse professionally with other members.

The origin of our own State Society dates back only to the year 1848, when the preëxisting county societies of Chester, Philadelphia, and Lancaster elected delegates to a Medical State Convention that assembled in the city of Lancaster to take the necessary steps to create a State Society such as was required to form a part of the American Medical Association. With this object the Philadelphia County Medical Society, on February 5, 1848, elected as delegates to the Convention, Drs. Emerson, John Bell, B. H. Coates, George W. Norris, Henry H. Smith, Rutter, Shallcross, Henry Bond, J. Rodman Paul, and Isaac Parrish, [2] of whom the speaker alone remains an active member of this Society.

The proposition for the meeting of the Convention originated with the Chester County Medical Society; whilst the Lancaster County Society tendered the first invitation for its assembling in Lancaster. At this meeting, on April 11, 1848, in the Methodist Church of that city, the daily newspaper, called *The Lancaster County Farmer*, greatly aided the objects of the meeting by reporting its proceedings. The delegates to the Convention from the Lancaster County Society were: Drs. J. L. Atlee, Humes, Kerfoot, Duffield, Clarkson, and Emerson; and of these, our venerable fellow-member, Dr. Atlee, yet continues his active interest in our Society, the formation of which he greatly promoted by his professional influence, whilst illustrating the pleasures arising from the social intercourse of its members by a handsome evening entertainment at his own residence.

In its progressive development this Society, like all others, adopted as an integral portion of its constitution the Code of Ethics published by the American Medical Association, and again acknowledges its high estimate of the "old Code," and the incalculable benefits it has bestowed on the profession and the public.

[1] Article IX., Section II., By-Laws of American Medical Association.

[2] Philadelphia Medical Examiner, 1848.

This Code, now so widely recognized as an exponent of many professional obligations, was reported by the late Dr. Isaac Hays [3] (on behalf of a committee) to the National Convention that formed the Association, and was composed chiefly from a great number of Codes of the preëxisting county and State societies in the United States, as well as from the Code of Institutes and Precepts, prepared by Dr. Thomas Percival, of Manchester, England, that was published in 1803. The adoption, by the Association, of a series of rules for professional conduct that thus had the approval of the most eminent physicians of that period, and some of the sections of which were in the words of our distinguished citizen, Dr. Benjamin Rush, [4] may be cited as among the first fruits of the organization of the medical profession in the United States, and illustrates, as Lord Bacon suggested, "the good derivable from an association of kindred spirits in the formation of a society," as well as the truth of our national motto, "that in union there is strength."

At a period when rebellion to the regularly constituted authority of the profession, as organized in this country, is attracting even the attention of the daily press, it cannot be useless to recall the history and provisions of this Code, and to remind those who are now objecting to its beneficent laws, and endeavoring to substitute their individual sentiments for those of the profession regularly assembled and organized for the creation of an association in which they openly united, that they are risking the severance of professional connections that calmer consideration may hereafter cause them deeply to regret. If the progress of time and the wishes of a majority of the profession demand a modification of this Code, it should be accomplished in and by the Association that originated it, and not by any county or State organization that with extraordinary selfishness ignores the sentiments of their brethren in other States.

A question that has been warmly discussed in connection with this Code is the right of members of the American Medical Association or a county society to consult at the bedside or office in regard to the diagnosis and treatment of disease with those who practice and believe in an exclusive dogma, and especially that one revived by Hahnemann, of *similia similibus curantur*, or that "like cures like."

It matters little, in the consideration of this question, to ask how or why it arose. The propriety of such consultations is positively settled by the Code, and hence its repeal is advocated by that comparatively small number, especially in New York, who perhaps anticipate benefit from the change. Any one who reads the clause in reference to consultations will readily see that the Code recognizes the fact that two physicians, of different medical creeds, cannot agree on any question of pathology and therapeutics, when each is conscientious in the correctness of his own professional opinion. . . .

UTILITY OF THESE ANNUAL MEETINGS TO THE PROFESSION AND THE PUBLIC.

The influence exercised by these annual meetings of our Society is, however, by no means limited to medical ethics, but extends to the entire community, through the scientific work thus accomplished.

In reviewing all that this Society has done in the

[3] Prefatory Note to original Code, printed in 1848.

[4] Ibid.

last thirty-five years our increased knowledge of the best means of preventing or alleviating disease is very apparent.

No post-graduate course of medical instruction, now so much in vogue, "with doctrines fashioned to the varying hour"[1] offers more valuable information to a medical man than that afforded by the papers and discussions presented in our sessions. The great difficulty at present is to condense the large amount of valuable material annually presented, and he who would not be left behind in the improvements of his profession cannot safely neglect attendance on these meetings or fail to read our printed Transactions.

Since 1848 many advances in pathology as well as in practice have been made in this body and been subsequently developed for the public good.

In the annual addresses of the chairmen of the Sections on The Practice of Medicine, Surgery, Obstetrics, and Hygiene, how much valuable information has been laboriously gathered by their respective authors, tested by their ripe experience, and freely offered to the profession and the public in the most attractive and scholarly manner, presenting facts not readily obtainable by those educated sons of toil, the hard-worked, badly paid, and ever-busy country practitioners, as well as by their more favored brethren in our cities, whose constant occupations leave but a brief hour to read up the improvements presented each day by a prolific press.

In the annual reports made by the able chairman of the Section on Hygiene, and especially by him who has also for years faithfully served the Society in the care of its funds, how many suggestions have tended to secure the comfort and sanitary safety of many of the towns and villages of this great Commonwealth.

In 1875, in inaugurating these reports on Hygiene, the chairman[2] aptly described "the absolute necessity of corporeal sanity to the existence of mental sanity," recognizing the great truth that the preservation of health implies the prevention of disease, and illustrating the ancient proverb, "mens sana in corpore sano," as well as the wisdom of Hippocrates, who nearly twenty-five hundred years before him first enunciated the principles of public hygiene in his treatise Περι αερος, υδατων και τωπων, — air, water, and localities, — principles yet carefully studied by our profession for the especial benefit of every community, thus realizing the truth of the anecdote of the Scotch doctor, who, being called on at a supper for a toast, gave "The health of this company, though very much agin my interest."

How much of the attention now given by laymen to the purity of the water they drink, the vitiation of the air they breathe, the importance of proper drainage, and the removal of excreta are due to the assembling of our various medical societies. . . .

From the annual meetings of our Society have also arisen many legal acts relating to the protection and preservation of some of the most valuable interests of the community, — acts, it is true, only gained from our Legislature by persistent efforts. In the Act for the Registration of Births, Marriages, and Deaths, now in general use in Philadelphia, how valuable a record is secured in tracing relationship or recovering property for otherwise unknown heirs.

The law requiring every physician to be registered by the prothonotary of his county, and the exhibition of his diploma before he can be allowed to practice medicine or issue a single prescription, has worked much good to the community, but it yet requires increased power. In those States that can enforce a thorough law it has driven away many of the harpies that, under the pretense of curing disease, preyed upon the credulous.

(To be concluded.)

THREE CASES OF HOMONYMOUS HEMIANOPIA.[3]

BY O. F. WADSWORTH, M. D.

THE cases which I have to report are of interest from the fact that, while in all the occurrence of hemianopia was sudden, in two this was attended, or followed, by only very slight other symptoms of cerebral disturbance, which in one, if not both, were quite temporary, and in the third there was no other symptom whatever. Hemianopia, as an accompaniment of other disorders of cerebral origin, — hemiplegia, hemianæsthesia, aphasia — is, as is well known, not uncommon, probably in a certain number of cases it is present without being recognized. But as an isolated symptom, appearing suddenly, without paresis or disturbance of sensation, it may be regarded as infrequent. I have found only some half dozen such cases reported, in a somewhat carefal examination of the literature of the subject. Most of these cases are, like my own, incomplete, — there was no autopsy. Two, in which there was an autopsy, are of special importance in connection with the localization of the lesion causing the hemianopia.

Mr. N., aged sixty, was seen in consultation December 30, 1881. He was a large, fleshy man, smoked to excess, but was in other respects temperate, though perhaps a large eater. He was subject to dyspepsia. For ten or fifteen years he had had occasional slight, momentary attacks of vertigo. He had for a long time occasionally waked suddenly from sleep with a feeling as of stoppage of breath, over so soon as fairly awake. Three weeks and a half before I saw him, on going to bed at night, he suddenly remarked to his wife that she had turned out the gas, it being still lighted. He was much excited by this, and his wife and daughter were up with him for perhaps two hours calming him, but I did not learn positively whether the loss of sight had continued so long or only his excitement. The following day, at least, there was no complaint of disturbance of sight, but for the next few days there was a tendency to coldness of hands and feet. Four days after this attack he rose from his chair, poured out and drank off a full glass of ice-water, became immediately much congested in the face, had some vertigo, and complained of blur of vision. Since then he had been confined to his room, most of the time to bed; his pulse had been intermittent at times, and there had been a murmur following the first sound of the heart, but he had improved with the administration of digitalis, and when I saw him the pulse was regular and strong. His memory, his physician thought, was a little affected; he would ask the same question sev-

[3] Read before the Boston Society for Medical Improvement, May 12, 1884.

eral times in the course of the visit; the daughter said she had noticed something of this tendency to repeat questions during all the past autumn; I did not observe it. It may have been in part nervousness; he had been very nervous about himself, and I was introduced as if my visit was unpremeditated, and was asked not to question him closely to avoid exciting him. He had complained from the time of the attack of a sort of blur before his eyes, "as when one looks at the light and then away;" he told me his "vision was not quick;" said, pointing to the door, which was a little to his left as he lay, "I would walk against that door if I tried to go out of it." His vision seemed good, however; he could tell time by the clock on the mantel, some fifteen feet off, and he could read, though "something troubled him in reading." The eyes were externally normal. The retinal veins looked rather dark (the superficial veins of the hands were also dark), but there was nothing else to be seen in the fundus of either eye to suggest any pathological condition. The patient sat or lay with his right side toward the edge of the bed, the other side of the bed being near the wall of the room, so that nearly the whole room was either directly in front of him or to his right side. Nothing had occurred to suggest to me hemianopia, and it was as a matter of routine that I tested his field of vision. The examination was made roughly with the moving hand, and hurriedly, so as to avoid causing alarm. The left half of each field was wanting, the right half apparently unaffected. My diagnosis was probable cerebral embolism.

I have not again seen Mr. N., but have recently heard indirectly that he gave up his business and moved into the country, that he has become rather cross and peevish, but in other respects is in fair health. His hemianopia has continued.

Mr. A., aged fifty-nine, has been for thirty years yard-master at the terminus of one of the railroads leading out of Boston. Eighteen years ago he was struck on the back of his head by a moving car, and was unconscious for three or four hours. At that time he was kept from his work for three weeks, but afterwards was as well as ever. He had had no other serious disturbance of health. He is a large man, of florid complexion, averaging two hundred and twenty-five pounds in weight. In July, 1883, after his usual exposure to the sun on a very hot day, he came home at noon with flushed face, and complaining of dizziness and headache, eat no dinner, but went back to the yard and attended to his customary work in the afternoon. When he reached home at night he told his wife that on the way he had run into people on the left side because he did not see them. His headache was worse, his face flushed, his pulse rapid and full. All uncomfortable feelings were relieved by a saline cathartic, bromide of potassium, and rest, but the defect of vision persisted. He was away from work only two days at this time, but a few weeks later took a vacation of a month. With this exception he had attended to his regular duties and been in his usual good health till I saw him, on March 19, 1884.

The eyes were externally normal, the pupils reacting well. Vision of either eye, with $+48$, $\frac{1}{\infty}$—$\frac{1}{\infty}$. There was complete loss of vision on the left side of the field in both eyes; on the right side no contraction of the field could be made out. The boundary of the defect was sharply defined, practically vertical through the fixation point, but with a slight curving out round the point of fixation toward the side of the defect. When he fixed a black dot on white paper at 16″, the black point of a pencil, approached from the left in the horizontal meridian, was seen only when it had arrived within a quarter or three eighths of an inch of the dot; from a little above or below the horizontal meridian the pencil was seen only when it reached the vertical meridian.

Placed 9′ from the blackboard, a white object was seen with the left eye about two inches to the left of the fixation point in the horizontal meridian; with the right eye in the same meridian at 3″ to 4″ to the left; above and below the line ran along the vertical meridian for the right eye; for the left eye coincided with the vertical meridian below, but above inclined very slightly toward the left. The media were clear; the disks a trifle grayish in both eyes, but not beyond the physiological limit for his age; the fundus generally quite normal in appearance.

Mrs. M., aged fifty-four, applied to me April 12, 1884, with complaint of loss of sight of the left eye, as she expressed it, which had occurred suddenly on February 23d, seven weeks before. For sixteen years she had been subject to attacks of sciatica, chiefly on the left side, at intervals varying from two or three weeks to three or four months, the pain situated in toe, heel, leg, or thigh, lasting from a day or two to two or three weeks, and at times severe enough to require subcutaneous injections of morphia two or three times daily. Her daughter, who came with her, spoke of slight hæmorrhage from the lungs on two occasions some years ago, but Dr. Hanscom who had attended the family the past eight years, writes me he had never heard of any such hæmorrhage, that he had looked upon her as a woman of rather delicate health, but always about the house and at work. He had attended her through a mild attack of pneumonia several years ago, and had been called to see her several times when suffering from sciatica. Some eleven weeks before I saw her she had an attack of severe sciatic pain in the left leg, with some tenderness in the knees, and considerable fever. She had morphia subcutaneously for the pain, and for two or three days a small amount of salicylate of soda, but as this last remedy disturbed her stomach, quinine, two grains four times daily, was substituted for it. At this time there was complaint of pain in the head near the temples, and of noises in head and ears, as of machinery. Both these symptoms ceased after a few days, though the quinine was continued some time longer. A day or two after relief of the sciatica, and a week from its beginning, pneumonia developed at the base of the left lung. She got on very well with this, and there was nothing specially noticeable in the course of the sickness except that convalescence was retarded by great and continued prostration. Improvement had been manifest for some time, however, when the defect of vision set in.

On the morning of February 23d she was lying in bed, having been awake perhaps an hour. The nurse gave her her medicine (syr. hypophos. co.), and went down-stairs to bring her breakfast. "Before the nurse could have got down-stairs" sight was completely gone on the left side, without any other sensation whatever, except a faint glimmering, which seemed to be chiefly or wholly on the left side. By April 12th her general health had improved, but the condition of the eyes had not changed, unless it were that the glimmering had been a little more pronounced the last three or four days.

The eyes were externally normal. Vision, R., with $+30, = \frac{1}{3}$; L., with $+24, = \frac{1}{4}$. The fundus was quite normal in both eyes. The left half of the field of vision was wanting for both eyes. The limit between the seeing and non-seeing halves was sharply defined. Measured on the blackboard at a distance of 14″ the dividing line ran an inch to an inch and a half to the left of the point of fixation, above and below it ran vertically and a very little to the left of the vertical meridian. The outer boundary of the right side of the field in each eye was normal.

At the present time it may be assumed that a partial decussation of the optic nerve fibres at the chiasma is accepted with practical unanimity, at least by ophthalmologists, and that the production of homonymous hemianopia (the only pure form, that is, in which there is stationary defect of the whole of corresponding halves of each visual field) must be ascribed to an injury farther back than the chiasma.

Two principal views have been held as to the course of the tractus fibres backward. According to the one view, of which there have been some variations, the scheme proposed by Charcot being probably the best known, a second partial decussation takes place at some point after the tractus has reached the brain. In Charcot's scheme the fibres which come from the outer part of the retina, and which do not cross at the chiasma, do cross to the opposite hemisphere after they have reached the cerebral ganglia, so that eventually all the fibres supplying the retina of each eye are connected with the hemisphere of the opposite side. If this scheme be correct homonymous hemianopia can be caused by a single lesion only if it involves the tractus between the chiasma and the point where the second decussation occurs. The scheme was originated to account for amblyopia of one eye from affection (hysterical) of the opposite hemisphere without abandoning partial decussation at the chiasma. Since it has been demonstrated, however, that in these cases there is not unilateral amblyopia, but that both eyes are affected, though in unequal degree, Charcot is said to have abandoned his scheme, at least to have indorsed an essay of his pupil, Féré, in which the latter proposed to give up the supposition of a second partial decussation. But aside from this there is now ample evidence against the accuracy of Charcot's view.

According to the other and most generally received opinion all the fibres of each tractus which are concerned in vision pass backward to the cortex of the hemisphere of the same side. In favor of this course of the fibres there appears to be convincing testimony.

Let me sketch very briefly the path the fibres follow on their way from the chiasma to the cortex. The tracts diverge from the chiasma, pass outward and backward beneath the crura cerebri, and curve upward around these. The main body of the fibres of each tractus then passes around and through the corpus geniculatum externum into and over the surface of the posterior part of the optic thalamus, and from the latter fibres pass on to the anterior corpus quadrigeminum. From these three ganglia, again, fibres run backward to the cortex of the occipital lobe. The inner portion of the tractus separates from the rest before reaching the corpus geniculatum externum, and most of it may be traced into the corpus geniculatum internum and posterior corpus quadrigeminum. Still another, innermost, fasciculus of the tractus enters the crus cerebri and goes, as Stilling states, to the ganglion of Luys, situated in the crus. According to Wernicke, who is supported by the results of Gudden's experiments on animals, these inner portions of the tractus have no anatomical or physiological connection with the eye; they do not pass into the optic nerves.

The evidence that the cortical centre of vision is in the occipital lobe is such as can scarcely be doubted, and is of various kinds. First, from the result of experiments on animals, especially the careful and repeated experiments by Munk on dogs and monkeys, in which the effect on vision produced by removing portions of the occipital lobe on one or both sides was studied. And although it may never be justifiable to draw from animals absolute deductions as to the conditions existing in man, such investigations are of great value when considered in connection with the data given by pathological examination. Among the evidence furnished by pathological anatomy are two cases reported by Huguenin.[1] The one was a man, fifty-three years of age, who had been blind of the left eye since his fifth year, and died of pneumonia. At the autopsy there was found circumscribed atrophy of the cortex in the posterior median part of the occipital lobe on either side, — much greater on the right, in agreement with the fact that the number of fibres that cross at the chiasma is greater than that of the non-crossing fibres. The other was a woman of forty-three years, nearly blind of both eyes from early childhood, and dying of typhoid. Here, too, there was atrophy of corresponding parts of both occipital lobes. Finally, there are now a number of cases recorded in which there was hemianopia, and in some of which the only lesion, in others the only lesion that could have caused hemianopia, was situated in the occipital lobe.

It is clear that homonymous hemianopia may be produced by an interruption in the course of the nerve fibres anywhere from the chiasma to the cortex. The question arises whether it may be possible to localize the interruption. For this purpose the path of the fibres may be divided into four districts: the first embracing the tractus from the chiasma to the central ganglia; the second the central ganglia, optic thalamus, corpus geniculatum externum, and anterior corpus quadrigeminum; the third the region extending from the central ganglia through the posterior part of the internal capsule; while the fourth extends from the point where the visual fibres separate themselves from all others to the cortex of the occipital lobe.

When, in addition to hemianopia, there are disturbances of sensation or of motion, or of both, the problem is a complicated one. There may be multiple lesions, or, if only one, a part of the disorders may be merely indirect consequences of it. The question is simpler if the hemianopia is the one important loss of function, when, as in the cases above reported, the onset of hemianopia is sudden, and there are no other symptoms, or at most only such as are temporary and of small moment. It is this simpler question alone that I propose to discuss.

Theoretically it would seem as if a lesion to produce such a result must almost necessarily be in the course of the optic tract, and, indeed, within the tractus itself. It can hardly be conceived that a hæmorrhage outside the tractus of sufficient amount to wholly cut off conduction by pressure could fail to excite also other grave symptoms of cerebral disturbance. Hæmorrhage,

[1] Centralblatt für pract. Augenheilkunde, 1878, page 311. Corresp. f. schweiz. Aerzte, 1878, No. 22.

embolism, or thrombosis within the tract might produce complete hemianopia and nothing else, yet, so far as I have been able to learn, there is record of no autopsy to show this has ever taken place. Its possibility, of course, cannot be denied. Partial destruction of the tract by embolism or thrombosis has been observed. Marchand [1] reports a case in which, three days before death, and when the patient was in a condition that must have prevented anything like accurate examination, right-sided hemianopia was said to have been observed. Here, besides other lesions, among the rest thrombosis of the left internal carotid, there was an area of softening in the left tractus due to embolism or thrombosis. The softening involved but about one third of the thickness of the tractus, however, and certainly could not, as Marchand states, have entirely interrupted its function. The hemianopia must, therefore, have been incomplete. Doubtless injuries within the tractus have been sometimes overlooked, and many cases never come to autopsy. Cases of sudden blindness of one eye have been supposed, with some likelihood, to be caused by hæmorrhage into the optic nerve, and the same thing might take place in the tractus, yet there is an anatomical difference in the circulation of the two parts of some significance in this respect. An artery and a vein of relatively considerable size, the central vessels of the retina, run for some distance within the optic nerve. The tractus, on the other hand, like the greater portion of the nerve, is supplied only by quite small vessels. The fact remains that positive evidence in this direction has not yet been presented.

So far as the central ganglia are concerned, their anatomical relations make it at the least extremely unlikely that a lesion could occur there of sufficient amount to produce complete hemianopia without, at the same time, impairing motility and sensation, one or both. The posterior portion of the optic thalamus, the pulvinar, is probably the most important of these ganglia for the function of vision. From Flechsig's investigations it appears that the thalamus is connected with all parts of the cortex by fibres which pass outward in all directions from its external surface, and make up in large degree the corona radiata. The most accurate pathological evidence as to the effect of localized disease in this situation is furnished by a case reported by Hughlings Jackson,[2] the autopsy by Gowers.

A man, aged sixty-five, in November, 1871, felt sick, vomited, attempted to go up-stairs, fell, and became unconscious. He was "unconscious" for two weeks, and for six weeks too ill to be left night or day. In March, 1873, there was a trifling drawing of the face to the right. He could execute all large movements of the upper limb, but they were all imperfect, feeble, and slow. The leg was more paralyzed than the arm; he could walk, however, a great distance. There was great diminution of sensation of the left side of the face, trunk, and limbs. There was left hemianopia. This defect of vision he found out when he recovered consciousness. In 1874 his condition was practically the same. In the early part of this year he had what was probably a slight paralytic attack, but no clear account of it was obtainable. It left no obvious permanent effects. Some time later the man died after a few days' illness, which, from his friends' account, presented no further definite local symptoms of nervous origin. Examination of the brain revealed but one lesion.

"The right optic thalamus presented a considerable depression over its posterior half, where it was much softer than that of the opposite side. On section the tissue was seen to be softened, grayish-yellow in tint. The amount of softening was greatest on the inner side, the posterior tubercle (pulvinar) being broken down and destroyed, and here the softening extended up to the ventricular surface. It did not extend beyond the limits of the thalamus into the white substance of the hemisphere or the crus, and the anterior half of the thalamus and posterior extremity of the corpus striatum were intact. The microscopic characters were those of simple softening. The vessels at the base of the brain were moderately atheromatous; no occluded vessels near the softened area could be discovered. Convolutions healthy. No disease elsewhere."

On the other hand, in a case reported by Baumgarten, in which there was a small cicatrix near the centre of the optic thalamus, no mention is made of motor or sensory affection. Baumgarten's personal knowledge of the case, however, was limited to the condition after death; the history is given with extreme brevity, and the publication was made to show the connection between the hemianopia which had existed and another and more extensive lesion. It is more than likely, therefore, that motor or sensory defect was present at some time, but was omitted in the relation. A detailed account was promised in *Graefe's Archiv.* It has not been given there. This case will be referred to again later.

The fibres going from the central ganglia concerned in vision to the cortex are, in their path through the internal capsule, closely associated with fibres connected with other functions. It must be assumed, then, that a sudden lesion in this position which produced total hemianopia would give rise to other disturbances of function also — hemianæsthesia and hemiplegia.

But recently has attention been strongly directed to the occipital lobe as the seat of the injury in hemianopia, yet there are, as has been said already, several cases in which it has been demonstrated that the defect of vision was caused by a lesion in that locality. In most of these, as was naturally to be expected, this was not the only symptom pointing to a localized disorder. A destruction of the lobe of sufficient extent to excite abruptly complete hemianopia cannot always be strictly limited, and in some instances the other disturbances were doubtless merely its indirect results. There is, however, one case (Curschmann's [3]) where the patient was under observation at the time hemianopia appeared, and until his death not long afterward, in which this was the only symptom of local, the one important symptom of any, cerebral disease.

A man of fifty years, previously quite healthy, was brought to the hospital three days after swallowing by mistake sulphuric acid. He presented the usual symptoms of sulphuric acid corrosion, and, as he could not swallow, was nourished by enemata. The circulatory apparatus appeared normal. A week after admission embolism of the right brachial artery occurred. The morning of the next day the patient complained that he could see nothing in the left side of the visual field. Examination discovered that the left half of the field

[1] Archiv für Ophthalmologie, xxviii., 2.
[2] Lancet, August 29, 1874, and May 22, 1875.
[3] Centralblatt für Augenheilkunde, 1879, page 181.

in each eye was wholly wanting, while central vision, eccentric vision in the right half of each field, and the fundus of both eyes were wholly intact. The hemianopia continued unchanged till death. No other symptoms of a localized disease in the brain appeared neither hemiparesis nor disturbance of sensibility; there was only slight delirium, which had not been present before the hemianopia was observed. After lingering in a very miserable condition, with difficulty in swallowing and vomiting of blood, the patient died of inanition sixteen days after the onset of the hemianopia.

The autopsy showed the ordinary changes in the intestinal tract; inflammation of the intima of the aorta propagated from the œsophagus; a firm embolus of the right brachial artery; finally, in the brain, — while cerebellum, tractus opticorum, fundus of the eyes appeared normal, — a large patch of softening in the right occipital lobe, which extended to the surface and was situated mainly at the median side and apex of the lobe.

Here the slight delirium, of later date than the embolism, and most naturally to be regarded as a result of it, might well have been a consequence of the general condition of the patient, who was practically starving.

Baumgarten's case,[1] previously alluded to, is not so clean as the preceding one.

A strong healthy man, having made a long, cold journey, noticed the next morning on rising a great disturbance of sight. This proved to be a complete left hemianopia, the boundary line of the defect in both eyes sharp and passing vertically through the fixation point. V = 1, and perfect color sense. The visual defect persisted unchanged till death, which occurred after some months from failure of heart. In the course of the disease symptoms of severe heart and kidney affection appeared. The one important lesion was an old so-called apoplectic cyst in the substance of the right occipital lobe. This was of the size of a walnut, its lower wall separated from the cavity of the right posterior cornu by a layer of intact white substance several millimetres thick, its upper wall formed mainly of the windings of all three occipital convolutions, which had wholly undergone yellow softening, but whose configuration was still recognizable. There was also a spot of red softening, the size of a pea, in the roof of the left anterior cornu, and a small so-called apoplectic cicatrix, half the size of a lentil, near the centre of the right optic thalamus. Optic nerves and tracts, crura cerebri, corpora geniculata externa and interna on both sides, chiasma and corpora quadrigemina were normal macroscopically and microscopically.

In Haab's case [2] a woman, aged sixty-one, had endo- and pericarditis. This was soon followed by temporary paresis of the left extremities and a left-sided hemianopia which persisted till death, about a year later, from mitral insufficiency. The apex of the right occipital lobe was found somewhat shrunken, the pia passing loosely over a collection of clear serous fluid. Examination showed softening and destruction of a pretty large district of the cortex, involving the whole neighborhood of the sulcus hippocampi over a space of several square centimetres. The anterior end of the defect was six centimetres from the apex of the occipital lobe.

Vertically the degeneration measured two to three centimetres. The sulcus hippocampi together with the bordering gyri were destroyed. The destruction was confined chiefly to the cortex, so that between the cystic softening and the posterior cornu there was a fairly thick layer of white substance. No other pathological change in the whole brain. Region of thalamus, corpora quadrigemina, corpus geniculatum externum, and tractus on both sides completely intact. There was no other lesion to account for the paresis which was present for a short time after the embolism, so that it is to be assumed there was disturbance of the circulation in croscope discovered no atrophy of optici, chiasma, or the motor region of the right hemisphere. The mitractus.

Other cases might be cited; these are perhaps the most striking.

From the absence of demonstration of a sufficient lesion within the tractus, and the evidence offered by such cases as have been quoted, it may not unjustifiably be assumed that when homonymous hemianopia occurs as an isolated defect the seat of the injury is to be found in the occipital lobe.

RECENT PROGRESS IN PATHOLOGY AND PATHOLOGICAL ANATOMY.[3]

BY WILLIAM F. WHITNEY, M. D.

CONTRIBUTIONS TO THE PATHOLOGICAL ANATOMY AND HISTOLOGY OF BERI-BERI.

Scheube [4] has had opportunity to make autopsies in twenty cases of this disease, which is endemic in Japan, Batavia, and Java. In all cases the nerves showed more or less degeneration and atrophy, the degree of this corresponding with the paralysis observed during life. The fresh nerves were hardened in osmic acid, and the microscopic examination of these specimens showed that the medullary sheath was swollen and destroyed by its division into larger and smaller drops. Fatty degenerated cells appeared, which, with the axis cylinders, were finally absorbed leaving simply the empty and collapsed sheath of Schwann. On cross section of the hardened nerves there was seen a more or less marked increase in the fibres, which varied considerably in their thickness, and between which lay groups of degenerated ones. This was shown by the coloration with carmine, which did not permit any distinction between medullary sheath and axis cylinder to be made out, as is seen in normal cases. The number of nuclei of the endoneurium was increased, and there were inflammatory changes about the vessels in the midst of the bundles. In chronic cases there was an increase of the connective tissue trabeculæ within the nerve trunks.

The branches supplying the muscles were the most changed, although some purely sensitive nerves were also affected.

Degeneration of the muscles goes hand in hand with that of the nerves. This is an atrophy and fatty destruction of the fibres with an increase of the nuclei. Frequently it appears as a colloid-like metamorphosis. The fibres become thinned, homogeneous, and have a tendency to break up into fibrilles. In place of the fibres which are destroyed appear newly-formed nuclei and later connective tissue. Thickening of the vascular walls is also present. The final result is a cirrhosis of the muscles similar to that of the nerves The atrophied muscles are marked by their pallor and yellow color.

[3] Concluded from page 253.
[4] Virchow's Archiv, vol. xcv., p. 146.

The spinal cord gave evidence of venous hyperæmia of the meninges with a serous effusion into the peridural and subarachnoidal spaces. It has been usual to regard the cord itself as affected in this disease, but the fact that the intensity of the symptoms noted during life and the amount of softening found after death stand in no direct relations causes the author to regard this as a post-mortem phenomenon due to the hot climate.

In six cases the entire cord was examined. In two there were great numbers of small corpora amylacea throughout the whole extent, but without any other observable change. In another case there was an atrophy and partial disappearance of the ganglion cells of the anterior cornua, but this is regarded rather as secondary. In the other cases the appearance was perfectly normal.

In three cases the nerve roots going from the lumbar region were examined and found normal. In a fourth case, where the process, in the peripheral nerves and muscles was most pronounced, these roots as well as the ganglia belonging to them were infiltrated with nuclei.

From the above observations there is no doubt that there is a multiple neuritis, and the author proposes the name of neuritis multiplex endemica for the disease.

The nerves of the heart were examined, and slight changes detected in them; single fibres in which the medullary sheath had separated into balls. The same was also noticed twice in the branches of the vagus, and once in the recurrent laryngeal and pulmonary nerves. Had the changes in the pneumogastric been as extreme as in the peripheral nerve fibres, there is no doubt but that death must have occurred much earlier in the course of the disease than is usually the case.

In acutely fatal cases there is a sudden distention of the lungs, with an increase of the subjective symptoms. The area of the heart's dullness becomes less, and finally disappears, while the lower boundaries of the lungs extend further backwards accompanied by tympanitic resonance. At the autopsy there was more or less extensive emphysema, especially of the anterior edge and apex. This is thought to stand in some relation to the lesion of the pulmonary nerves already described.

The ordinary condition of the brain was that of venous hyperæmia of the meninges and of the substance of the organ, with œdema of the pia mater. With an increase of the ventricular fluid there was associated œdema of the cerebrum.

The muscles of the heart were fatty in all cases. In seven this was moderate; in the others it was extreme, or even enormous. Usually diffuse, it never presented the marbled, or speckled look characteristic of pernicious anæmia. The right ventricle was more affected than the left, although the reverse relation occasionally presented itself. Together with this there was twice found a colloid-like degeneration of the fibres. The alterations in the nerves are considered to be the cause of these degenerations. In two uncomplicated cases there were evidences of inflammation either as a diffuse interstitial infiltration, or as small, disseminated foci. The blood was fluid, and the thrombi described by the older writers are probably of post-mortem origin. A light atheroma of the aorta was present in about one-half the cases.

Hyperæmia and œdema of the lungs were found, and occupied a varying distribution and intensity.

The liver and kidneys were filled with blood in consequence of the general venous congestion, and there was granular and fatty degeneration of the cellular elements, often to be distinguished by the naked eye Small hæmorrhages in the pelvis of the kidney were twice noted, and in a number of cases a general increase of the nuclei. In the liver these latter lay partly in the interlobular tissue and partly in the acini. In the kidney they were, as a rule, beneath the capsule. In one case, complicated by typhoid, small abscesses were present in the renal substance.

The spleen was always more or less enlarged, but as malaria was present in the region too much weight should not be attached to this fact.

Venous hyperæmia, varying in extent and variety, with occasional small hæmorrhages beneath the mucosa, was seen in the intestinal tract.

Hydropericardium with general œdema was of very frequent occurrence.

The infectious nature of beri-beri is very probable, although as yet no parasite has been found. For this speak (1) the granular and parenchymatous degeneration of the solid organs; (2) the inflammatory foci in the heart and muscle; (3) the existence of a splenic tumor in the acute cases.

A FATAL PEMPHIGUS-LIKE DERMATITIS WITH CHANGES IN THE NERVOUS SYSTEM.

Meyer [1] records a case which can be briefly summarized as above, and of which the following is a short history, with a description of the anatomical changes: —

An apparently healthy man was attacked by what was considered as eczema. At the end of four weeks papules, irregularly distributed, appeared on the nates and lower extremities, and gradually assumed the characteristics of pemphigus. The general condition of the patient was unsatisfactory. The appetite was soon lost, the pulse became rapid, and the temperature exhibited an evening exacerbation; sleep poor, and the urine loaded with urates. The strength declined, and the base of the bullæ did not become covered with epidermis as in ordinary pemphigus; in fact, loosening of the epidermis progressed unrestrained, then the epidermis began to scale off in large flakes without the accumulation of any amount of fluid beneath. It recalled the process in the skin after a severe burn. Within seven weeks death followed. There were symptoms referable to the central nervous system.

Histological Examination. If a section through the periphery of one of the parts deprived of its epithelium be examined with a low power, the corium was the part which had suffered most extensively. Its upper layers from the point where the process began were infiltrated with round cells, most numerous in the neighborhood of the vessels and the papillæ. This infiltration was superficial. The sweat glands were intact.

The papillæ were enlarged, swollen, and clubbed at the extremities. The blood-vessels were partly injected and partly occluded by new cells.

In places where there was deep destruction the papillæ were entirely wanting, leaving a nodular granulating surface, pierced here and there by the openings of the sweat glands.

The horny layer of the epidermis failed entirely over the diseased portion, on the edges of which were

[1] Virchow's Archiv, vol. xciv., p. 185.

irregular-shaped fragments, from the covering of the ruptured bullæ. The separation had evidently taken place at the summit of the so-called stratum granulosum. In places the points of the papillæ projected quite bare, and where the epidermis was preserved pus cells were freely intermingled.

Nearer the edge of the cellular infiltration and also deeper down beneath the glands were met numerous clear spaces without proper walls, or at most covered with a thin endothelium. These were partly empty and partly filled with a homogeneous coagulated mass, and must be regarded as lymph spaces.

Of the small arterioles lying deep in the cutis and subcutaneous tissue a large number were affected to a high degree by endoarteritis or entirely obliterated. In a small nerve trunk nothing but a slight thickening of the sheath could be detected. With higher powers many of the vascular loops of the papillæ or intervening tissue were bloodless with transparent walls, or else filled with a homogeneous or slightly granular mass presenting the appearance of a hyaline thrombus.

The other organs of the body were normal.

The nerves were further examined after treating with osmic acid. In the small subcutaneous nerves of the forearm, of the back of the foot, and of the thigh there were found numerous nearly empty sheaths, containing a number of nuclei and scattered drops of myeline. Some of the fibres were fatty degenerated in a marked degree. In many the medullary sheath was broken up, there was an accumulation of granular protoplasm with an increase of the nuclei about the sheath of Schwann. At some parts of their course the tubes are entirely collapsed, at others filled with granular myeline or a protoplasm rich in nuclei. Here and there had been formed regular granular corpuscles which lined the empty sheaths of the affected nerves.

The sciatic as well as the brachial plexus showed similarly affected fibres, while in the different muscular nerves they were wanting.

The sympathetic as well as the spinal ganglia were unchanged.

On the other hand the cord showed a marked alteration. Gray streaks could be seen along the posterior longitudinal fissure throughout the entire cervical and dorsal region; further grayish-yellow spots in the posterior bundles in the upper cervical, as well as transparent points in the lateral columns of the lower dorsal and lumbar regions. With the microscope the interstitial tissue was found to be everywhere thickened, and the nerve tubes surrounded by a rigid connective tissue, which was strongly colored by carmine but was very poor in nuclei. Lines of sclerotic tissue were found along the blood-vessels, which were thus rendered impervious. The nerve fibres were either affected singly or in groups, and were often so atrophied as to be recognized only as small colored points. This process was confined chiefly to the posterior and lateral portions of the cord while the anterior columns remained intact. In the gray substance the ganglion cells were found to be markedly pigmented, as is often the case in old people.

In this case we are not authorized to assume at once a direct connection between the sclerosis of the cord and the affection of the skin, since there is another process at work which may stand in a causal relation to both: namely, the obliteration of numerous vessels both in the spine and in the skin. This is all the more remarkable as there was not the slightest trace of such endo-arteritis obliterans in any of the internal organs. It may be considered that the alteration in the vessels, which had persisted for a long time, gave rise to nutritive changes, and this led, as is so frequently the case in the cord, to sclerosis of the connective tissue. When this had become dense enough a compression of the nerves resulted, and from this central disturbance changes were set up in the skin, which soon reached an unusual and fatal intensity, from the impairment of nutrition due to the arterial obliteration.

Naturally this is but an hypothesis, and further investigation must show what connection coincident destructive changes in the vessels of the skin and nervous centres can have.

Reports of Societies.

THIRTY-FIFTH ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

THURSDAY, MAY 8TH. THIRD DAY.

The Association assembled at the usual hour in the morning, and prayer was offered by Rev. Dr. Paret.

Dr. Keller, on a question of privilege, asked the Association to change the Secretary's Report, thus enabling the Nominating Committee to designate a time for the annual meeting, according to an amendment to the By-laws adopted at the last meeting. This was granted.

A Nominating Committee, as follows, was appointed to fill vacancies in the Board of Trustees of the Association's *Journal:* Drs. Ferguson, New York; Briggs, Tennessee; Reeves, West Virginia; Prewitt, Missouri; Peck, United States Navy; Russell, Missouri; Stormont, Kansas.

MEDICAL MUSEUM AND SURGEON-GENERAL'S LIBRARY.

The Committee on the Army Medical Museum and Library of the Surgeon-General's Office reported that Congress had been memorialized in behalf of a suitable fire-proof building and increased annual appropriations. The only result had been a favorable report from the Committee of the House for an appropriation of $10,000 for the Library. The Committee was continued.

SCIENTIFIC RESEARCH UNDER GOVERNMENT PATRONAGE.

Dr. George M. Sternberg, U. S. A., offered the following resolutions:—

Resolved, That we earnestly petition the Congress of the United States to make suitable appropriations for the prosecution of scientific researches relating to the causes and prevention of the infectious diseases of the human race, to be expended under the direction of the National Board of Health; and that a permanent detail of one medical officer of the army and one of the navy be authorized for the prosecution of researches of this nature.

Resolved, That a committee of five members of this Association be appointed to present copies of these resolutions to the Speaker of the House of Representatives, to the President of the Senate, and to the chairmen of the Committees on Public Health of the House and of the Senate.

The resolutions were adopted, and the President appointed the following gentlemen the committee: Dr.

Sternberg (chairman), Dr. Albert L. Gihon, U. S. A., Dr. I. M. Hays, Philadelphia, Dr. J. C. Dalton, New York, and Dr. J. E. Reeves, West Virginia.

CREMATION.

DR. KELLER, of Arkansas, presented a resolution to the effect that in a few years the cremation of the dead would be regarded as a sanitary necessity, that the decision of the courts had pronounced this method legal, and that from hygienic, religious, and sentimental stand-points this method of disposing of the remains of the dead was the best. Dr. Keller said that the remains of the late Dr. Gross were now on their way to be cremated, and asked for the adoption of his resolution. The chair ruled that the resolution was out of order because it introduced new business.

THE INTERNATIONAL MEDICAL CONGRESS, 1887.

The Committee appointed to consider a resolution inviting the International Medical Congress to meet in this country in 1887, reported through their chairman, Dr. Billings, a recommendation that a committee of seven (with the President, Dr. Flint) be appointed to invite the Congress to meet in Washington, and, if the invitation be accepted, that this committee act as the executive committee of arrangements, with power to add to its number, elect its own officers, and draw upon the Association for necessary expenses for a sum not exceeding five hundred dollars.

REPORT OF THE TRUSTEES OF THE ASSOCIATION'S JOURNAL.

DR. J. M. TONER, of Washington, chairman of this board, read a report on the financial condition of the Association and of its *Journal*, now published in Chicago. The *Journal* as now published gave six times as much reading matter yearly as was contained in the former transactions. It was believed there would remain on hand at the end of the financial year $500 over and above the expenses. Dr. Toner thought the receipts had been kept down by the restrictions on advertising. The editor's report, read by Dr. Toner, stated that estimates had at first been made on the basis of 2500 subscribers, but that the actual circulation had been 3436, of which 3271 were among members and subscribers. The advertising had been slowly increasing, and the whole amount received from this source was estimated at $3000. The total income for the year had been $18,547.50. Dr. Davis believed that the financial condition of the *Journal* was such as to enable him, should he continue to be the editor for another year, to widen its scope of usefulness by engaging correspondents in more of the large cities, and to justify him in devoting more time to its editorial management.

In the opinion of the Trustees, the report of the editor showed the *Journal* to be in a satisfactory condition; it had been conducted with economy, ability, and judgment; the best interests of the Association had been kept in view, and its dignity maintained with rare discretion. It is believed that the experience gained during the past year, with the increased funds, will enable the editor to do better work in the future. In April of this year Dr. Davis had presented his resignation, but after correspondence with the Trustees he consented to withdraw it. Dr. Davis had informed them that while he would do the best he could for the *Journal* during the coming year, at the end of that period he would absolutely resign. Bids received from various firms for the publication of the *Journal* for the coming year were none of them as advantageous as those of the present publishers, and they had again been given the contract.

A minority report on the *Journal* was presented by DR. JOHN H. PACKARD, of Philadelphia, who began by stating his conviction that he could in no other way discharge his duty as a trustee. He did not desire to reflect on his colleagues, and was not hostile to the editor. He was influenced by no personal motive other than the warm interest he had taken in the success of the enterprise for the past four years, and he certainly had no desire to hamper it in any way. He had, however, understood that the financial condition of the *Journal* was really straitened, and that the editor had not drawn his salary. Of this he strongly disapproved. Moreover, he dissented from the majority report not merely from a financial point of view. The *Journal* had not even approached the standard which the organ of the Association should attain. He did not forget the difficulties confronting a new enterprise of this kind, but the defects of this publication were not those of youth, and were not decreasing. The object of the *Journal* should be not merely to spread out the minutes of the Association or papers read over one year. The object should be to make a strong, wide-awake, high-toned periodical, well equipped in every respect to be a medium of communication between members all over the country, and not a sectional or partisan organ of the Association. A thoroughly trained corps of editors is requisite. Access must be had to large libraries, where there is also opportunity to secure auxiliary work, and contributions should be liberally paid for. Facilities for mechanical execution are essential to real success. Of these requirements scarcely any seem to have been possessed. Due respect for the interests of the Association compelled him to state this as his sincere and deliberate judgment. He therefore recommended that the resignation of the editor, Dr. N. S. Davis, be accepted, and the publication of the *Journal* be transferred to some Eastern city, Washington, Philadelphia, or New York.

A motion to lay the minority report on the table was carried by 191 ayes to 74 nays, and a motion to adopt the majority report was put and carried.

OFFICERS FOR THE ENSUING YEAR.

The Committee on Nominations reported through its Chairman, Dr. Hooper, the following list of officers for the ensuing year: —

President. — H. F. Campbell, M. D., of Georgia.

Vice-Presidents. — J. S. Lynch, M. D., of Maryland; D. D. Mercer, M. D., of Nebraska; J. W. Parsons, M. D., of New Hampshire; H. C. Ghent, M. D., of Texas.

Treasurer. — R. J. Dunglison, Pennsylvania.

Librarian. — C. H. Kleinschmidt, District of Columbia.

Chairman of Committee of Arrangements. — S. D. Logan, New Orleans.

Secretary. — W. B. Atkinson, Pennsylvania.

Assistant Secretary. — W. H. Watkins, New Orleans.

Judicial Council, to fill vacancy, 1886, J. K. Bartlett, M. D., of Wisconsin.

To fill vacancies caused by expiration of term of service: J. H. Murphy, M. D., of Minnesota; J. M.

Toner, M. D., of Washington; W. Brodie, M. D., of Michigan; H. D. Holton, M. D., of Vermont; A. B. Sloan, M. D., of Missouri; W. B. Ulrich, M. D., of Pennsylvania; W. M. Beach, M. D., of Ohio.

OFFICERS OF SECTIONS, AND COMMITTEES.

Practice of Medicine. — H. D. Didama, M. D., of New York, Chairman; G. M. Garland, M. D., of Massachusetts, Secretary.

Obstetrics. — R. S. Sutton, M. D., of Pennsylvania, Chairman; J. T. Jelks, M. D., of Arkansas, Secretary.

Surgery. — Duncan Eve, M. D., of Tennessee, Chairman; E. B. King, of Pennsylvania, Secretary.

Ophthalmology. — Joseph A. White, M. D., of Virginia, Chairman; Eugene Smith, M. D., of Michigan, Secretary.

Diseases of Children. — John H. Pope, M. D., of Texas, Chairman; S. S. Adams, M. D., of District of Columbia, Secretary.

State Medicine. — E. W. Schaeffer, M. D., Chairman; J. M. McCormick, M. D., of Kentucky, Secretary.

Oral and Dental Surgery. — A. W. Harlan, M. D., of Illinois, Chairman; J. Ewing Mears, M. D., of Pennsylvania, Secretary.

Trustees of Journal. — H. F. Campbell, M. D., of Georgia; J. H. Packard, M. D., of Pennsylvania; Leartus Connor, M. D., of Michigan.

Necrology. — J. M. Toner, M. D., of District of Columbia, Chairman.

Committee on Necrology. — C. H. Franklin, M. D., Alabama; W. N. Yates, M. D., Arkansas; W. R. Clump, M. D., California; Charles Dennison, M. D., Colorado; C. W. Cranzoni, M. D., District Columbia; J. G. Thomas, M. D., Georgia; J. H. Hollister, M. D., Illinois; J. F. Hibbard, M. D., Indiana; C. V. Motram, M. D., Kansas; D. S. Reynolds, M. D., Kentucky; B. A. Ashby, M. D., Maryland; H. O. Marcy, M. D., Massachusetts; W. F. Brenkey, M. D., Michigan; A. J. Stone, M. D, Minnesota; Dr. Smythe, Mississippi; R. C. Moore, M. D., Nebraska; Stephen Wicks, M. D., New Jersey; J. Lewis Smith, M. D., New York; E. E. Graves, M. D., New Hampshire; F. E. Larrimore, M. D., Ohio; I. Minis Hays, M. D., Pennsylvania; W. E. Anthony, M. D., Rhode Island; T. T. Robertson, M. D., South Carolina; D. D. Saunders, M. D., Tennessee; —— Harris, M. D., Texas; C. M. Chandler, M. D., Vermont; H. M. Clarkson, M. D., Virginia; W. F. Van Kirk, M. D., West Virginia; J. K. Bartlett, M. D., Wisconsin; W. R. Forward, M. D., United States Navy; N. L. Bates, M. D., United States Navy; H. W. Austin, M. D., United States Marine Hospital Service.

METEOROLOGY.

The Committee on Meteorology reported through its chairman, DR. N. S. DAVIS, that the observations on the relations of meteorological conditions to acute diseases had been but few, owing to the lack of general interest in the matter. The investigations regarding ozone and organic matter had been carried out systematically in the past year, and the results were published, in part, in the *Journal*. Dr. Davis recommended that the work of the committee be continued.

COLLECTIVE INVESTIGATION OF DISEASE.

As chairman of the committee on this subject DR. DAVIS reported in favor of accepting a proposition from a similar committee of the British Medical Association in favor of coöperation, and recommended the appointment of a central committee of seven members, with power to appoint a sub-committee in each State, to correspond directly with the British Committee on Collective Investigation. A sum, not exceeding $300, should be appropriated to enable the central committee to inaugurate the work. The same cards and blanks might be used by the two Associations. The report and recommendations were adopted.

The Judicial Council made a short report on matters of discipline.

The Address in Surgery was read by title only, the subject being The Effects and Results of Operations for the Relief of Gunshot Wounds of the Small Intestine.

The Association then adjourned to Friday.

THE AMERICAN LARYNGOLOGICAL ASSOCIATION.

SIXTH ANNUAL CONGRESS, HELD IN THE CITY OF NEW YORK MAY 12, 13, AND 14, 1884.

FIRST DAY. MORNING SESSION.

THE Association met at the hall of the New York Academy of Medicine, and after the roll-call listened to an Address of Welcome by the President, DR. FRANCHE H. BOSWORTH, of New York, who at its conclusion read a paper on

THE CLINICAL SIGNIFICANCE OF FIBRINOUS EXUDATIONS UPON THE MUCOUS MEMBRANE OF THE UPPER AIR-PASSAGES.

The following conclusions were arrived at by the author: —

(1.) That a fibrinous exudation which occurs in the crypts of the follicles of the faucial or pharyngeal tonsil or mucous membrane of the lower pharynx has no tendency to extend, and characterizes a disease which is self-limited and not dangerous to life.

(2.) That a fibrinous exudation which occurs upon the surface of the tonsil or of the mucous membrane of the fauces constituting a croupous membrane, so called, presents gross appearances by which it can be unmistakably recognized.

(3.) That a croupous membrane in the fauces of an adult marks the existence of a disease which, while being undoubtedly a blood-poison, is still a self-limited infection, and which involves no danger to life.

(4.) That a croupous membrane forming in the fauces of a child marks the occurrence of the same disease as croupous membrane in an adult, but in the child there is the additional danger of a new centre of development arising in the larynx, where it may involve the greatest danger to life, but entirely as a mechanical obstruction to breathing.

(5.) That a diphtheritic membrane developing in the fauces marks the occurrence of a disease which is dangerous to life, not only from primary and secondary blood-poisoning, but also from the tendency to the development of the same morbid process in the larynx.

Mucous membrane that was in a state of acute catarrhal inflammation offered, he thought, a favorable nidus for the occurrence of diphtheritic deposit without there being any necessary connection between the two

processes. The catarrhal condition was not, in his opinion, the prodromal stage of the diphtheria.

DR. BEVERLEY ROBINSON made some extended remarks in which he took exception to many of the views presented by Dr. Bosworth. Thus with regard to the question of follicular tonsillitis, the pathological appearances of the exudation from the interior of the follicles did not resemble microscopically the condition to which Dr. Bosworth alluded in speaking of the true croupous membrane. There was found simply cheesy masses which were pressed out from the interior of the crypts and did not in any sense partake of the nature of an exudation which was usually regarded as fibrinous. With regard to the question of croupous tonsillitis, he said that while there were, perhaps, many cases in which the membrane itself did characterize the type of a disease which was only of a certain local quality, yet he had seen cases in which the mucous membrane did not seem to be incorporated with the false membrane itself, where the affection seemed to be of mild type, but after a few days they became of a very serious character, the membrane, which at first had been white and easily detached, becoming dark and so firmly adherent to the underlying tissue that he could not then say the case was not one of diphtheria. He thought that there were a certain number of cases ordinarily called croupous tonsillitis, which in all probability began, as stated by several authors (among them Dr. DaCosta), in a herpetic eruption of the tonsils. As to the origin of these affections in the local absorption of certain germs, while the President's views, shared by many others, might have a theoretical basis, they were in his own mind far from being proven. Unquestionably we did find in such affections of the air-passages the presence of bacteria, but the microscope might fail to show the slightest difference in their appearance whether they were present in one affection or another, and we were unable to say whether such germs were active in carrying the poison or whether they were entirely innoxious.

DR. W. C. JARVIS said that he could for the most part substantiate the views of Dr. Bosworth as regards the gross pathology of the exudation met with in the upper air-passages. Several years ago his attention had been first called to inflammation of the pharyngeal tonsil by the occurrence of the affection in his own person. His inference as to the complication of the third tonsil was afterward verified by repeated observations upon numerous subjects of the disease. A feature of acute follicular pharyngitis which did not seem to have received any attention was one in which the secretion was retained, eventually escaping upon rupture of the membrane, and covering the pharynx with a white membrane. Such a change did not occur when the inflamed follicles remained patent.

DR. F. I. KNIGHT said he wished to call attention to an important practical point which he thought was quite apt to escape the attention of physicians, and that was the increased susceptibility to diphtheritic infection during the existence of any simple acute inflammation of the air-passages. Hence, however mild the latter might be, he thought it advisable to give a guarded prognosis.

DR. S. W. LANGMAID thought that at the beginning there might be the symptoms of only a simple pharyngitis, while in reality the case began as one of diphtheria, its true nature being masked until later.

The PRESIDENT said that the point made in his paper was that a membrane in a state of acute inflammation offered a better nidus for the germ which developed the diphtheritic or croupous process than did the healthy membrane. He felt called upon to take exception to Dr. Robinson's view that follicular tonsillitis was ever characterized by cheesy deposits in the crypts of the tonsils. The resemblance of the pathological characteristics of the exudation to those of croupous membrane on the surface was sufficiently close to warrant us in the conclusion that the two conditions were very nearly allied, if not identical, the difference being only such as we would expect to find from the difference of location in the two deposits. In some cases, indeed, the membrane overflowed the crypts, as it were, and spread out on the surface, constituting a membrane in the true sense of the word. He wished particularly to emphasize the point that we could by examination throw a great deal of light on the clinical tendencies of inflammatory diseases of the fauces. As regards the matter of germinal ætiology, it seemed to him that in the absence of any more definite theory this presented the best explanation of the facts noted.

DR. JOHN N. MACKENZIE, of Baltimore, read a paper entitled

A CONTRIBUTION TO THE STUDY OF CONGENITAL SYPHILIS.

In the first part of it he detailed with great minuteness a case which had come under his observation. The child remained in a healthy condition from the first to the third year, when the first trouble to develop was interstitial keratitis of both eyes. Both eyelids also became paralyzed, and there was intense occipital cephalalgia, which lasted over a month. This was before Dr. Mackenzie saw the case, but under intelligent treatment these symptoms subsided, though the child was left with internal strabismus of the right eye and deafness of the right ear. Afterwards it suffered from violent ulcerative inflammation of the pharynx, tonsils, and larynx, and extreme ulceration of the hard palate, with dysphagia, complete aphonia, and profuse and continuous muco-purulent discharge. While all these troubles were still increasing in severity the patient was taken with a mild attack of scarlatina, which had a most salutary effect upon all the lesions and symptoms. There were two features which he thought were of special interest in this case. First, while deep ulceration of the lower pharynx was not rare in congenital syphilis, such a degree of stenosis as existed in this case was very unusual. Second, the paralysis of both upper eyelids, which was undoubtedly of cerebral origin, and probably depending on the presence of gummata.

Further experience, Dr. Mackenzie went on to say, only served to strengthen the force of his convictions on the subject of congenital syphilis of the throat as he had expressed them in an article published in the *American Journal of the Medical Sciences* for October, 1880, in the course of which he had said that a great deal of obscurity still prevailed concerning these palate-pharyngeal ulcerations in consequence of a persistent adherence to the old superstition that referred them indiscriminately to scrofula; an examination of the subject showing that syphilis, tuberculosis, and lupus were all alike ascribed to it. But, excluding lupus, tuberculosis, and certain other rare forms of ulceration, he had maintained that deep palate-pharyngeal de-

struction in children was nearly always the result of syphilis.

Dr. Mackenzie then announced the following propositions: —

(1.) That in congenital syphilis deep ulceration may invade the pharynx and naso-pharynx.

(2.) That when the eruptions of inherited syphilis are apparently delayed the pharyngeal and laryngeal complications are apt to be more severe.

(3.) That females are more frequently attacked with throat ulcerations than males.

(4.) That ulceration may occur in any situation, but its favorite situation is the palate, and especially the hard palate.

(5.) That when ulceration occurs at the posterior part of the hard palate the tendency is to involve the soft palate and velum.

(6.) That the next most common seats of ulceration in their order of frequency are the fauces, naso-pharynx, posterior pharyngeal wall, nasal fossæ and septum, the tongue and the gums.

(7.) That ulceration, especially that of the palate, shows a disposition to centrality of position together with a special tendency to caries and necrosis of the bone.

(8.) That the tendency to necrosis exists at all periods of life, but especially in early youth, at which period it is more destructive and less amenable to treatment.

(9.) That whilst deep pharyngeal ulceration generally precedes or coexists with similar affections of the larynx, the latter occurs too without evidence of pre-existing pharyngeal lesions.

(10.) That laryngeal ulceration does not commonly follow the pharyngeal destruction of so-called latent syphilis, those palato-pharyngeal ulcerations found in tardy congenital syphilis having little tendency to invasion of the larynx, but rather to infiltration of the naso-pharynx and nose.

(11.) That simultaneous or consecutive ulceration of the palate, pharynx, and nose seems to be characteristic of syphilis, or at least seems to occur more frequently in this than in any other disease.

While the throat ulcerations of congenital syphilis showed a tendency to produce rapid destruction of tissue, and were often uncontrollable by medicinal measures, the lesions sometimes subsided as if by magic on the occurrence of severe acute exanthematous disease, the poisons of the two affections being apparently mutually destructive. These remarks did not apply to diphtheria, however, as this disease seemed only to aggravate the existing troubles, and the patient usually succumbed rapidly to its attack; but between congenital syphilis and such acute fevers as scarlatina, measles, and chicken-pox there appeared to be a well-marked antagonism.

The paper was discussed by the President and Drs. Shurley, Hartman, Knight, and Donaldson, and the opinion of the writer in regard to the identity of syphilitic and so-called scrofulous ulcerations of the throat was in the main sustained by the speakers, Dr. Knight calling special attention to the great difficulty, if not impossibility, of getting at a syphilitic history in many cases. In reply to a question of the President, Dr. Mackenzie said that in the treatment he relied mainly on mercurial inunction and the internal administration of iodide of potassium; and Dr. Bosworth then said that he had of late years been gaining increasing confidence in the use of mercurials, rather to the exclusion of the iodide.

Appointment of Committees.

The Chair appointed on the Nominating Committee Drs. F. I. Knight, of Boston; George M. Lefferts, of New York; and J. Solis Cohen, of Philadelphia; and on the Auditing Committee Drs. J. N. Mackenzie, of Baltimore; and F. H. Hooper, of Boston.

Election of Fellows.

There being two vacancies in the membership of the Association, which is limited to fifty, Drs. Clarence C. Rice, of New York, and J. Solis Cohen, of Philadelphia, were elected Fellows. The thesis submitted by the former was entitled The Diagnostic Value of Pathological Appearances, and that of the latter A Case of Anchylosis of the Left Crico-Arytenoid Articulation.

First Day. Afternoon Session.

A paper on

Retro-Pharyngeal Abscess

was read by Dr. J. O. Roe, of Rochester, N. Y. He said that the post-pharyngeal cellular tissue was specially liable to abscess from its looseness and comparatively low vitality. Retro-pharyngeal abscesses were divided into two varieties: those originating in the soft tissues, and those originating in disease of the cervical vertebræ. The former variety again were divided into classes: those originating in the glandular structure, and those originating in the cellular tissue. Having given a sketch of the anatomy and glandular connection of the parts, he gave a list of the causes to which retro-pharyngeal abscess had been attributed, dividing them into three classes, — idiopathic, traumatic, and secondary. In speaking of the diagnosis he stated that the condition was to be differentiated from croup, the presence of a foreign body, œdema, pharyngeal tumors, and enlarged tonsils, and that by inspection and digital examination the trouble could usually be readily recognized. The prognosis when the abscesses originated from disease of the bone was unfavorable, and when originating in the soft tissues was least fatal in cases of the idiopathic variety. The only treatment was opening the abscess and evacuating its contents, and for this purpose, as a rule, he preferred a small incision at first, as recommended by Albert, as presenting less liability of the pus getting into the larynx and trachea; afterwards enlarging the opening so as to make the evacuation complete.

This affection was one which occurred for the most part in infants and young children; fully one half of those reported having been in the first year of life. Dr. Roe then gave the histories of three cases which he had seen in consultation. The first two of these occurred in infants under one year, and in both the trouble had been attributed to diphtheritic croup. He operated in the way mentioned above, and in each instance complete and instant relief was afforded. The third case occurred in a young man twenty years of age, who died from exhaustion on the third day after the abscess was opened. Here the pus burrowed downwards behind the œsophagus.

Dr. DeBlois said he had been very much interested in Dr. Roe's paper, evincing, as it did, the result of much laborious research, and particularly because he had himself had three cases. One had been in an adult,

and the two others in children, and in one of these the incision had to be carried through the posterior pillar of the fauces. He differed with Dr. Roe as to the size of the incision, and thought that it should be free, so that the pus could be at once evacuated. After the incision the head should be forced down, and if in a child the patient should be inverted. He thought the position of the head, which he had always found carried very far back in retro-pharyngeal abscess, should be laid stress upon as a point of diagnosis.

DR. GEORGE M. LEFFERTS thought that this affection was much more rare than was generally supposed. He did not believe that it was ever caused by nasal catarrh; for if this was the case it would be very common. Neither did he believe that it was ever due to pharyngeal tuberculosis or injury of the posterior wall of the pharynx. It was probably due to a simple phlegmonous inflammation of the cellular tissue arising from causes which produced abscess elsewhere. The diagnosis was perfectly simple, by inspection and digital exploration, and the treatment was to be founded upon precisely the same surgical principles on which abscess elsewhere in the body was treated.

DR. GEORGE W. MAJOR stated that the first case under his notice occurred in a child four years of age as a sequence of measles. Dyspnœa and dysphagia were very marked, but instant relief followed excision and evacuation of the pus. The second case, which followed after cerebro-spinal meningitis, and was attended by the most urgent symptoms, was also immediately relieved by opening. A third case had been referred to him by an ophthalmic surgeon as one of retro-pharyngeal abscess, and although palpation did not bear out the presence of pus he made an exploratory incision, cutting into an evidently malignant growth. Eighteen months afterward the patient died, when a large sarcoma was found occupying and absorbing a large portion of the base of the skull and pressing on the brain.

DR. R. P. LINCOLN related a case illustrating the fact that other operative interference than simple incision of the posterior wall of the pharynx, in order to get rid of the contents of these abscesses, was sometimes necessary. On incising the abscess in the pharynx this part immediately collapsed, affording prompt relief from threatened suffocation; but there was no perceptible change in the size of two other tumors which caused bulging on each side of the neck under the angle of the jaws, though they seemed to be less tense. By introducing the aspirating needle into each they were readily evacuated, though on the left side it was necessary to repeat the operation twice.

DR. J. N. MACKENZIE called attention to the possibility of confounding a gummy, syphilitic tumor of the posterior pharyngeal wall with a retro-pharyngeal abscess, and related a case referred to him where the mistake had been made by a brother practitioner.

DR. E. F. INGALS related two cases occurring in his experience: one in a child ten months old, and the other in a man about fifty years of age. The latter came to him because of laryngeal trouble, and the retro-pharyngeal abscess, which developed slowly, opened spontaneously. Soon afterward the patient died of cerebral meningitis, and the cause of the abscess seemed to be the same as that of the latter.

DR. C. W. CHAMBERLAIN had also seen two cases. The first was of the ordinary character; but the second was apparently unique. The abscess was situated posterior to the left tonsil, and as the case was in the country its importance was not at first recognized. When urgent symptoms set in, Dr. Chamberlain was sent for, but did not arrive until too late. The abscess had opened spontaneously, and very profuse hæmorrhage, which quickly proved fatal, had ensued. The autopsy showed that the cause of death was rupture of the internal carotid artery from weakening of its walls by the abscess. The child was probably syphilitic, he thought.

The paper was also discussed by Drs. Jarvis, S. Johnston, and Cohen, and the discussion brought to a close by Dr. Roe.

DR. T. A. DEBLOIS, of Boston, read a paper on

CONGENITAL WEB OF THE VOCAL BANDS, WITH CASE.

The case was that of a female patient twenty years of age. Her voice was weak and puerile, and she stated that this had always been the case. She was first under the care of Dr. Farlow, his colleague, at the clinic where she was seen, and afterwards under his own. The patient had a very dependent epiglottis, and the parts were so sensitive that it was a considerable time before any view of the larynx could be obtained. It was then found that the anterior half of each vocal band was covered by a white web which extended between them. The intolerance of the larynx having after a time been in a measure overcome, Dr. DeBlois introduced a Mackenzie forceps with the idea of tearing the web apart, but only succeeded at first in scratching it. Afterwards, however, he was able to split it across, leaving a jagged, dentated edge on each side, but the next day he found, to his chagrin, that the torn surfaces had united. He then introduced a probe to break up the adhesions, and the treatment of expansion was afterwards continued by Dr. Farlow. As a result of these procedures the voice of the patient gained in register three upper notes and four lower ones. Having completed the history of the case, Dr. DeBlois said that the bibliography of the subject was meagre, and that he had been able to find only three similar cases recorded. These he quoted.

DR. M. J. ASCH said that he had met with one case which was not congenital, but the result of inflammatory action, and there was also a web of one eye. The patient refused operative interference.

DR. J. H. HARTMAN said he questioned the advisability of introducing and forcibly expanding a pair of lateral forceps in the larynx, and would prefer the use of the covered or tube bistoury for the division of webs.

DR. WM. H. DALY, of Pittsburg, read a paper on

GUNSHOT WOUND OF THE LARYNX, INVOLVING THE VOCAL BANDS.

He expected to have presented the patient to the Association, but he had been unable to attend.

DRS. J. SOLIS COHEN and M. J. ASCH spoke of the rarity of this accident. The former said that he once had the opportunity of seeing Dr. Daly's case, and at that time he doubted the correctness of the diagnosis; but the subsequent history proved conclusively that he had been mistaken.

DR. GEORGE M. LEFFERTS said that there was one specimen of gunshot wound of the larynx in his collection at the College of Physicians and Surgeons, but, unfortunately, there was no history with it. The ball had undoubtedly remained in the larynx, as a

tracheotomy wound was visible; the operation having probably been performed for the relief of dyspnœa.

The last paper of this session was by DR. J. SOLIS COHEN, of Philadelphia, and was entitled

A CASE OF COMPLETE PARALYSIS OF THE LEFT VOCAL BAND IN EXTREME ABDUCTION, THE RESULT OF AN INCISED WOUND OF THE NECK.

This he considered was a unique and extraordinary case. The wound, although the patient denied this, was undoubtedly suicidal, being made from behind forward. It severed the sterno-cleido-mastoid muscle, was deepest just in the track of the pneumo-gastric nerve. There had been complete aphonia ever since the injury, which was stated to have been received in November, 1883, and the left vocal band was found to be immovable in a position of extreme abduction, while the right band was normal. In forced inspiration the latter did not go as far out as the left constantly remained. The case and the somewhat obscure subject of adductor paralysis brought up by it gave rise to a discussion of some length by the Fellows, in which no great amount of light was thrown upon the matter. Dr. Cohen stated that he regretted very much that some of the gentlemen who had recently been attending the American Medical Association at Washington had not stopped over in Philadelphia, as he had urged them to do, so that they might see the case for themselves.

In the evening the President gave a reception at his house to the Fellows of the Association, at which many prominent medical men of the city were present to meet them.

(To be continued.)

PROCEEDINGS OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M. D., SECRETARY.

MAY 12, 1884. The President, Dr. CHARLES D. HOMANS, in the chair.

DIABETIC COMA.

DR. R. T. EDES reported the case. The patient had been in the City Hospital a year ago for the removal of a tumor in the leg, and afterward began passing much saccharine urine, became emaciated, and was admitted to the hospital a week ago. The diet had been rather limited, although the so-called diabetic bread, which is never entirely free from starch, had been allowed. Because of vomiting the diet had been for a short time even more limited.

Yesterday morning the patient got up and then went to bed again, and was found, at half-past nine, partly comatose, breathing deeply, but at the normal rate, with dull eyes, cold extremities, and livid hands and face, the hands being purple, but the face blue. Consciousness was not entirely gone, as an attempt to examine the eyes was resisted. Brandy and ether were injected subcutaneously, and later carbonate of ammonium and brandy were swallowed. Although the patient roused slightly, death occurred at eight in the evening, the temperature at no time rising above ninety-four in the axilla and ninety-five in the rectum. Five ounces of urine were got by the catheter, but it has not yet been examined.

Certain points in the case seemed to the speaker of interest. First, ether given under the skin in the morning was smelt in the breath three and a half hours after. Second, most cases ending in diabetic coma have made rapid progress. Here the disease lasted less than a year. Third, this patient had shortly before the attack had a senna injection which, as it proved, did not prevent its occurrence. Fourth, there had been no narcotic given. Last, the diet had been low and had been almost wholly meat. That had been advanced as a cause of diabetic coma. Dr. Edes had, on the other hand, seen a case in consultation with Dr. Post, in which the patient had been under observation and treatment for but a few days, and who nevertheless died in this way.

DR. BUCKINGHAM said that he had been called to see diabetic coma in a boy, from whose care he had been discharged some time before, and who had meanwhile, for some weeks and quite up to the time of the attack, been living largely on starchy food. The cause of coma cannot, always at any rate, be the exclusive use of an animal diet.

DR. O. F. WADSWORTH read a paper on

HEMIANOPIA.[1]

DR. G. HAY said that he was very glad to have heard this paper. The course of the optic nerve fibres in their continuation through the brain is an interesting subject. First, as a matter of anatomy. It is only recently that they have been considered to extend to the occipital lobe. Such a course of the fibres is not given in some comparatively recent text-books of anatomy. And this is not strange, for he supposes the fibres have not even yet been followed continuously through this course by the anatomical observer. The evidence that they extend to the occipital lobe is derived from clinical observation and pathological anatomy. The conclusion, however, is equally valuable, though arrived at indirectly.

Although at times we may be in doubt whether the cause of an hemianopia is in the optic tract or the occipital lobe, yet the knowledge of the position of the visual centre must contribute somewhat to the solution of the complicated problems of cerebral diagnosis.

A point of interest to him in this position of the visual centre, so remote from the eye, is that this is consistent with the doctrine that something more than the eye is concerned in vision.

This extended course of the optic fibres has some relation to the physiology of vision; and as this latter (vision) is a complex process, it may be, considering this complexity and the extent of the optic fibres, that all the parts of vision are not related in precisely the same way to the nervous apparatus.

Light and color may perhaps have some special relation to the retina, while the conception of form and distance may be more intimately associated with another part of the nervous apparatus. Then we have in vision, he thinks, a conviction of the objective reality of the thing seen, and also it is to be noticed that although memory is to be distinguished from vision and applies to other matters, such as sound and ideas, yet it is essential to the efficiency of our vision. For instance, if in all cases we failed to remember that we had ever seen an object before, such vision, divorced from memory, would be practically very different from what it is at present, and comparatively useless.

Differences of opinion exist with regard to the rela-

[1] See page 483 of this number of the JOURNAL.

tion of the mind to the brain, but the subject is an abstruse one, and probably requires for its solution considerations other than what we generally consider as merely physical.

Dr. Hay desired to express again his pleasure at having heard Dr. Wadsworth's instructive paper, and considered it as one not merely to be listened to once, but as deserving to be studied.

DR. J. J. PUTNAM spoke of the importance of the subject of vision to general practitioners. Cases sometimes occur in which early recognition is of value, as, for instance, after injury, when loss of vision may be hysterical, but hemianopia is not likely to be simulated.

He mentioned a gentleman who lost the power not of seeing, but of attaching significance to what he did see; who found that he could not read, and could recognize friends only with difficulty. Here was a lesion, functional indeed, in that part of the brain that attaches ideas to what is seen. The location of function may be of practical use, and ought to be the common property of the profession.

DR. EDES inquired of Dr. Wadsworth if it is settled that hysterical amblyopia is never confined to one side.

DR. WADSWORTH answered that he would not say that it is universally accepted, but that in all the reported cases examined by competent oculists it has been found to be double. It is usually greater in one eye than in the other.

He also referred to the case of word blindness mentioned by Dr. Putnam, and said he had recently seen, in an article in the *London Medical Record*, the statement that in such a case Charcot had found the only vision to be situated in the angular gyrus.

DR. W. W. TEMPLE reported four cases of

POISONING BY FUMES OF NITRIC ACID.

The cases resulted from the accidental emptying of a carboy of commercial nitric acid.

CASE I. Mr. I. S., aged twenty-four. Health good at time of accident (September 17, 1883). By mistake a carboy of commercial nitric acid (containing one hundred and sixty-five pounds) was brought to the store in which the young man worked. In attempting to get the box containing the carboy back on the truck the stopper came out, and the carboy emptied itself rapidly on the floor, and in attempting its removal the fumes of the acid were inhaled. The sensation was that of suffocation. He would rush out to the air for a moment or two and then return again. This was continuing for thirty to thirty-five minutes, after which the irritating effect passed off. Whilst in the air he felt quite himself. In about three hours he began to have a sense of constriction about the chest, with cough and pain on inspiration. On going home, his wife noticed his paleness and asking what was the matter, his answer was, "Nothing, only I feel so weak." During the afternoon and evening he coughed considerably with increased pain in the chest, and when seen for the first time on the next morning had the same symptoms. The paleness was a peculiar almost lemon tint. Examination of the lungs was negative. On the third day a few moist râles were noticeable all over the chest. Slight cough with pain on full inspiration, together with a feeling of weakness, were the only symptoms; these had left him at the end of the week, and had it not been for a large ulcer in the gluteal region (caused by falling into the acid) he could have resumed his work. As it was, he remained at home ten days.

CASE II. Mr. L., aged twenty-seven. Health good at time of accident. History of exposure same as previous case. Slight hæmoptysis twice during the day after the accident; then, as he expressed it, "he had a severe cold," which lasted two weeks. Good recovery.

CASE III. A gentleman, aged fifty-seven, exposed to the acid fumes for a few moments, had an attack of pneumonia, which his physician ascribed to that cause.

CASE IV. This is the case of special interest in the series.

Mr. C., aged fifty-four. Health always good, and at time of accident exceptionally so. Due to his interest in the store, his exposure to the acid was much more prolonged than any of the others. In endeavoring to remove the open carboy he slipped and fell, his face and mouth coming in close proximity with the mouth of the carboy; he must in falling have inflated the lungs to their fullest extent, and that with the strong acid fumes. He remained in and about the store until the danger was over, and then went to a neighboring clothier's to get new clothing. Returned to the store and resumed his work, feeling well.

About half-past one P. M. (four hours after the accident), not feeling "just right," he concluded to go out and take the air. Took a horse-car and came up to his brother's on Columbus Avenue. Whilst there he was evidently not feeling well, and first began to cough. Coughing was painful, and was increased by deep inspiration. He drank some tea, and at three P. M. walked, with assistance, to Dr. Temple's rooms (a distance of half a mile).

Face pale, and anxious expression. Pulse rapid and compressible, 124. Respirations rapid and shallow. This he explained as being due to the fact that deep breathing caused cough and the cough pain. He got a full dose of ammonium carbonate (ten grains). He asked about the possible dangers from the accident. After resting two hours he regained natural color. Pulse 90; better character. Complained only of feeling weak, and a tightness about chest. Cough much diminished. Then took horse cars to Old Colony Depot. In walking from the car to the depot noticed a dragging step, and that the cough was increased by exertion. Took train to his home at Neponset, driving to his house. In going from his carriage to the house noticed the same dragging step with evident loss of muscular power. During the night he coughed almost incessantly, expectoration being frothy and of a straw color.

Examination of chest negative.

September 18th. Toward morning he was much easier, coughing only occasionally. Took considerable milk (a tumblerful every hour for three hours). Pulse 90; fair character. Respiration 24. During the morning he continued comfortable, and took nourishment often.

Three P. M. Much the same condition. Pulse 94; fair strength. Respirations, somewhat more rapid, 28. Free from pain with the exception of a sensation of tightness about chest.

Half past five P. M. Pulse 120; feeble. Respiration 44. Coarse râles heard all over chest. At 6.15 he died.

Autopsy, forty-eight hours after death, by Dr. F. W. Draper.

Both lungs free.

Heart. Right auricle a little distended, but not engorged. In posterior wall of right auricle four small ecchymoses grouped. Whole heart retains blood which is of dark color and firmly clotted. Size of heart normal. Structure normal.

Endocardium — normal.

Lungs. External color of left lung rather darker than normal, pits on pressure, markedly œdematous and crepitant in every part. Bronchial mucous membrane but little reddened and with no apparent swelling.

Right lung. More deeply reddened, with more tendency to engorgement. Mucous membrane of larynx and trachea injected to a marked degree; just above the bifurcation of the trachea and at the opening of the right bronchus are four minute submucous ecchymoses, the largest the size of a pin's head.

Vocal chords free, and chink of glottis open.

Epiglottis. Its inferior surface shows marked congestion, and at its base several submucous ecchymoses, the size of a pin point.

Kidneys and *liver* injected.

Stomach, intestines, spleen, normal.

Christison and Taylor both report cases that are so similar to the last one that perhaps it would be interesting to review the notes on them.

In March, 1854, Mr. Haywood, a chemist, of Sheffield, England, lost his life under the following circumstances: He was pouring a mixture of nitric and sulphuric acids from a carboy containing sixty-five pounds, when by some accident the vessel was broken. For a few minutes he inhaled the fumes of the mixed acids; three hours after the accident he was sitting up and appeared to be in moderately good health. He was seen by a medical man, and complained merely of some cuts about his hands. Later he coughed violently. In three hours more there was difficulty of breathing with increase of the cough, also a sense of tightness at the lower part of the throat. At times he could scarcely breathe. He died eleven hours after the accident. Autopsy showed congestion of the trachea and bronchi, with effusion of blood. Heart flaccid, and contained but little blood. No record of condition of lungs.

The other case is as follows: A chemical manufacturer, in endeavoring to remove from his store-room a hamper in which some bottles of nitric acid had burst, breathed the fumes for some time, and was seized in four hours with symptoms of inflammation. At night his urine was suppressed, the skin became blue; at last he was seized with hiccough, acute pain in the diaphragm, convulsions, and delirium. Death in twenty-seven hours after the accident.

It had occurred to the speaker that death may have resulted from poisoning with nitrous acid, with which commercial nitric acid is contaminated.

The fact that there seems to be a delay in all the symptoms (in all the cases) of several hours he was at a loss to explain, as the effect from the nitrate as to time is not recorded. We may, however, conclude that the fumes are both local and central in their action; that the action is at first irritant to the lungs with a probably direct effect on the heart and muscular coat of the arterioles, and later a centric action on the cord, and that there is bronchial irritation, hyperæmia, and œdema of the lungs, and later pneumonia; also that in the cases there is a stage when there seems to be marked improvement in all the symptoms, giving, for the time being, hope to the physician and friends, but hurrying on later into disastrous and fatal results.

The treatment after removing the cause must be symptomatic. The post-mortem appearances to be expected are, as a rule, if death occur early before pneumonia has set in, only a more or less marked change in the organs of respiration, hyperæmia, swelling, ecchymoses, œdema of the lungs; sometimes possibly, fibrous membranes in the bronchi.

DR. F. W. DRAPER spoke of the great rarity of cases like those reported. He had been able to find only five cases recorded; and it was fair to Dr. Temple to remark that none of them compared with his in fullness and accuracy of detail with regard to the manner of the accident, the subsequent clinical history, and the post-mortem appearances. He regretted, however, that the blood and some of the tissues had not been submitted to chemical analysis. With regard to the writer's ingenious suggestion that the toxic effects might be due to nitrous acid in the system, Dr. Draper admitted that it was in harmony with the clinical data. To those who witnessed the autopsy in the fatal case, the comparatively insignificant changes observed in the air-passages were a surprise, and seemed to indicate that the fatal result had been due more to a general toxic action of the acid than to a simply local irritation.

DR. BENJAMIN CUSHING thought the treatment must be stimulant, with relief to suffering.

DR. CHARLES D. HOMANS referred to a case of Dr. J. M. Warren's published in the first volume of the Records of this Society. A negress swallowed some nitric acid intentionally, staining the inside of the mouth and fauces yellow, swelling the tongue, and causing some shock. There was at no time fever, and in eleven days she was well enough to be transferred from the Massachusetts General Hospital to the jail whence she had come. Two days later she died from hæmorrhage consequent upon a large rupture of the friable stomach.

INHALATION OF AMMONIA.

DR. C. W. SWAN reported the case for the sake of comparing it with those above.

A man of sixty-three was holding a pound bottle of strong liquor ammoniæ on his knees in a horse car on a hot day, when it exploded. He threw himself on his hands and knees in order to get air, as it seemed to him that the vapor shot upward and then fell in his face. The immediate distress for breath was great, and by the time he had reached the nearest drug store the inside of the mouth and tongue were much burnt and covered with white patches; the fauces were less red. He could hardly have swallowed any of the liquid, but there was burning at the epigastrium as well as severe frontal headache. Treatment was with dilute acetic acid at once, the speaker having been a passenger in the car with him. He lost his speech as well as appetite, and sonorous râles were heard. In a week these symptoms began to decline and œdema of the lung appeared. He fairly recovered in a month or six weeks.

— The fifth International Congress of Hygiene will meet at the Hague, August 21 to 27, 1884.

— To overcome the unpleasant odor of anæsthetics the suggestion is made to add a few drops of oil of cloves to chloroform, or one sixth part of cologne to ether, as they are being inhaled.

Medical and Surgical Journal.

No. 4 PARK STREET, BOSTON, MASS.

THE DIAGNOSTIC VALUE OF THE DISCOVERY OF THE "BACILLUS TUBERCULOSIS" IN SPUTUM.

SINCE Koch first announced his discovery of a micro-organism peculiar to pulmonary phthisis much wordy war has been waged as to the real existence of such a specific organism, as to its relation to the disease whether of cause or effect, as to the best methods for distinguishing the organism from others, and much of this discussion has been the offspring of theory rather than of practical experiments and observations. The determination of the diagnostic value of the presence of these bacilli in sputum is one practical point, and that of the degree of contagiousness of phthisis another, solutions of which would be a grateful conclusion to these discussions, and we welcome any practical work contributing to such ends. In malignant disease of the lung, chronic pleurisy, or chronic pneumonia, bronchiectasis, incipient phthisis, phthisis accompanied by extensive bronchitis, or by deep-seated changes obscured by surrounding emphysema, difficulties are met with by the diagnostician in dealing with which another arm of precision besides auscultation and percussion would be very gratifying.

Dr. Henry S. Gabbett publishes in the *British Medical Journal* (April 26th) a series of observations on the sputa in 110 cases of diseases of the chest made at the Royal Hospital for Diseases of the Chest, London, with a view to ascertaining the presence of Koch's bacilli.

The number of observations is, to be sure, not large upon which to base generalizations, but it is large compared to those hitherto offered by many taking part in discussing these questions, and the material at command and opportunities for discovering the precise condition of the patients were favorable.

Of the observations sixty-five represent those in which bacilli were found in the sputa, and forty-five those in which no bacilli were found. Of the first division fifteen were instances of the last stage of pulmonary phthisis, thirty were less advanced cases in which, however, "there could be no question as to the nature of the disease," and the remaining twenty were either examples of incipient phthisis or cases in which the diagnosis was very doubtful at the time of examination.

The forty-five observations of the second division represent instances of other diseases than phthisis, in all which the sputa were searched in vain for bacilli. Dr. Gabbett does not undertake to say that they did not exist, but that they could not be found.

The broad result of his experiments Dr. Gabbett states to be this: —

"The great majority of specimens of bacilli-containing sputa were from undoubtedly phthisical patients, and the remainder from persons who, in all probability, suffered from the disease; while the specimens of sputa free from bacilli were, as a rule, from cases where the lungs weere either healthy or affected by some totally distinct morbid process. The few exceptions to this latter assertion, and the instances in which the bacilli were repeatedly sought for in vain, and at length found at some later period, lead me to the conclusion that, while the presence of these organisms is, in all probability, positive evidence of phthisis, their absence under certain circumstances does not negative the existence of the disease. In this inquiry pulmonary phthisis was considered as one disease — the disease which, with great variations in its mode of onset and the acuteness of its course, tends to attack both lungs, commences with localized consolidation, passes on to softening and excavation, is attended by the train of symptoms known as 'consumption,' and presents certain common appearances after death."

The circumstances under which bacilli are not found in phthisical sputa are stated to be mainly as follows: (1.) When the patient is directed to cough and expectorate, very commonly the result of the examination will be negative; in all cases for examination it is well to wait for natural expectoration, that is, till the reflex action of coughing is excited by the accumulation of the contents of the bronchial tubes. When the cough is "dry," definite results are not to be expected. (2.) Bacilli are probably not present in the sputum at a very early stage of phthisis before there is any actual breaking down in the lung. (3.) The existence of general bronchial catarrh in a severe form may make it difficult to find the organisms.

If bacilli are found in the sputum the diagnosis of phthisis may be ventured upon, if they are not found its existence cannot absolutely be denied. If, however, they are not found after repeated searches under favorable conditions, in a case where there are definite signs of lung damage, or in a case whose duration would cause such disorganization to be expected somewhere, then one is justified in suspecting that some other than the phthisical process is at work or that the phthisical process has been arrested.

The conclusions that may be drawn from these experiments are thus summarized: —

"(1.) Koch's bacilli occur in the sputa of pulmonary phthisis, acute and chronic, in all its forms.

"(2.) They do not occur in the sputa of other common diseases of the chest.

"(3.) They may probably be found in every case of phthisis which has advanced to the stage of breaking down of tissue.

"(4.) The discovery of very few bacilli in the sputum conveys no certain information as to the gravity of the case. Their occurrence in enormous swarms in all probability denotes excavation."

SOME OLD EDINBURGH SURGEONS.

The addresses which some of the elders of our profession have the ability and the inclination to give regarding their personal experience of long-departed scenes and men often possess a charming quality. The jealousies, the triumphs, the asperities, the eccentricities of these heroes of a former generation come down to us mellowed by the recollection of their aged witnesses with something of the rich flavor of an old vintage. We make no apology for having from time to time outlined for our readers some of these sketches. The latest such record of personal reminiscence of old-time worthies that we have met is in the address by Dr. Alexander Keiller, President of the Harveian Society, delivered at the annual meeting, April 14th. It is devoted to memories of the Edinburgh physicians of fifty years ago, among them some whose names have become world-wide. The address is to be found in the *Edinburgh Medical Journal*. Dr. Keiller speaks from his own knowledge of the "Burke and Hare" matter, which in its time created such a furore. The obtaining of subjects for dissection was a difficult matter, and in the absence of anatomy acts the graveyards were often forced to give up their dead. Popular feeling was strong against the doctors. The carriers of boxes or chests in the vicinity of the University, especially after dark, were apt to be set upon. The cry of "*a shusey! a shusey!*" (vulgate for *sujet*) was always potent to raise a mob, and the porter (though perhaps bearing a perfectly innocent burden) was sometimes beset with such vigor that he might consider himself lucky not to be made a "shusey" himself. Burke and Hare were guilty of the horrible crime of waylaying, stupefying, and suffocating some thirteen victims, whose bodies were sold at £10 to £15 apiece for dissection to Dr. Knox. Hare turned king's evidence, and though Burke was apparently the lesser scoundrel he alone was hung. It was freely charged that Knox was cognizant of the source of his subjects, but no evidence of such knowledge was given. He was the object of great hatred, and was hung in effigy. Burke's body was exposed for two days to popular execration on a dissecting table of the University, and his tanned skin was made into purses which (hear it, ye shades of Tewksbury!) were in great demand, especially among the ladies.

The "field days" for operations in the amphitheatre were Sundays, and the numerous church-going students were wont to attend divine service in a church directly opposite the infirmary, where they sat in a gallery set apart for them. The minister was the most popular preacher in the city, and took a deep interest in the students' professional success. When the infirmary bell was heard, indicating that the operations were to begin, he (perhaps making a virtue of necessity) sat down until the gallery was emptied. The noise of the unceremonious stampede would probably have drowned his voice if he had attempted to continue preaching. "The rush from the gallery of that church," says the writer, "to the pit of the surgical theatre, in order to get a comfortable front seat so as to narrowly see the whole performance, was anything but calculated to increase the earnestness of our devotional exercises or more deeply impress us with the Gospel truths we had just listened to."

Liston and Lizars were the rival surgeons of that day. They gave a conjoint course on operative surgery, and when subjects were scarce there was some competition between them. Lizars was an exceedingly bold operator, and his attempts, even at that early day, in the line of ovariotomy made him very unpopular. He was nick-named "Ovary John," and was freely abused as being little better than a murderer. Yet in spite of abuse and opposition, of which Dr. Keiller remembered to have heard him bitterly complain, he persevered in what he believed would become a means of saving many lives, and is entitled to the honor of being foremost among the practitioners of that operation. Some basis for his butcherly reputation seems to have lain in his operating costume, which was, if not antiseptic, at least antihæmorrhagic. It consisted of a pair of very loose overalls, an old long-sleeved topcoat, buttoned up even beyond the throat, the better to prevent any possible spurting of blood reaching his shirt collar or necktie, which was never of the white choker stamp. His style of operating was very business-like, and his hangman garb was not out of keeping with the sanguinolent appearance customary to that small part of him which was uncovered by it.

Liston was, unlike Lizars, of a very powerful physique. A burly carter was brought into the amphitheatre one day with an unreduced dislocation of the shoulder. An attempt had been made by the other surgeons to reduce it, but had failed on account of the resistance which the fellow had made to every effort on their part. The man was finally led like a wild beast into the ring, when Liston pounced upon him, and at once firmly grasped the immovably dislocated extremity, which he proceeded to pull and twist, while the patient stormed, cursed, fought, and kicked. "Liston, however," says our author, "was quite equal to the awkward situation, and as every kick with dangerous force was launched at him in front, he knew his anatomy too well not to swing round so as to receive them on amply cushioned parts behind, until his own time came to return the madman's blows and imprecations with confounding, and, at the same time, most successful interest; for, while engaged keeping up the extension required to overcome, if possible, the muscular contraction in order to facilitate the reduction aimed at, Liston knowingly and cleverly seized his opportunity, the most precious opportunity in such cases, of staggering the muscles into comparatively flaccid abeyance. Liston, while keeping up the extension with one of his big and powerful fists, and fiercely eyeing his still cursing and kicking surgical victim, loudly exclaimed, 'You d——d scoundrel, what are you swearing at?' and with one momentarily-released mighty right hand struck him a bang between the eyes, when immediately, through Liston's masterly manœuvering, in popped the stubborn joint of the now bunged-up-eyed carter, who obviously failed to

appreciate either the laughter or the applause of the audience."

Liston seems to have had besides the strength of a lion something of that beast's disposition. He resented anything that seemed to compromise his dignity. In one of his summer clinical lectures he was speaking of the tourniquet, and its best and most applicable forms, and then exhibited a specimen which he had newly invented, and the power of which he set about showing on his own person. The instrument was on the principle of an ordinary double-padded hernial truss, with an unusually strong spring. This he managed, by using considerable force, to bend round his enormous thigh so as to reach the region over the femoral artery, and, after showing both before and behind how well the two pads fitted, it caused him no small difficulty in again releasing himself from their firm pressure; and when striving with considerable force to rebend the powerful spring, the back pad got hold of the gluteal region of his thin, light-colored, drawerless trousers, it so extensively gave way as to show, and that in the most bare-hipped fashion, the enormous extent of his lower and posterior proportions, which unlooked-for exhibition could not and did not fail to receive rounds of applause as well as side-splitting laughter. One luckless youth near the lecturer was detected stuffing his handkerchief into his mouth to suppress his laughter. A few days later this young man was invited to hold a limb of a subject which had attained a green old age, while Liston amputated. The latter did not care to touch the limb save with his amputating knife, which, however, played about the fingers of the merry young man till it accidentally drew blood. The youth looked woefully at the surgeon, who laughingly exclaimed, "The more you bleed the better." Whether the young man was right in his opinion that this was done in retaliation for his own ill-timed hilarity was never known, but it is pleasant to learn that a cleverly-drawn water-color of one of Liston's most noted operation cases presented by the young man to the surgeon made the two friends.

Liston and Lizars often had difficulty in getting subjects for their conjoint course, and, it would also seem, in dividing the subjects they did get. Once it was agreed that Liston should have the next one that arrived. It came in a "chest of tea" all the way from Ireland. Lizars knew it was on the way, but said nothing. Liston would not have discovered its arrival had not a mob seen it, and attacked the carrier, who was protected only by the arrival of a constable. Of this part of the story Lizars was ignorant. He told one of the students if Liston came to the building to say that he (Lizars) had gone away, and would not return for some time. Liston arrived to claim his subject, and even while the lying message was being given, Lizars, with incautious haste, peeped over the stairs in his dissecting gown, and said "Is he away?" Of course the cat was out of the bag at once. Liston, with a "You lying little devil," threw the offender over his shoulder, and carrying him up to the dissecting room landed him with a shake in the middle of the floor, to the amusement of the students and of Lizars.

Such a story shows as well as anything the change in public sentiment from a day when such petty tricks could be resorted to between two leading teachers in a great university. So does also the fact, which our author considers not only true, but a matter of no surprise, that Syme *bought* the chair of clinical surgery from its former occupant, Russell, for £300 a year. That is, he paid that sum to have Russell retire at a time when the latter's influence would be able to put Syme, to the exclusion of any of his rivals, into the professorial chair.

We may at some future time give our readers the benefit of more of Dr. Keiller's reminiscences.

TESTAMENTARY CAPACITY.

DURING the last week in April two interesting will cases were contested in our Massachusetts courts. One was that of Cooley Dickenson, and the other that of James Fitzgerald.

An unsuccessful effort was made to break both of these wills, chiefly on the score of mental unsoundness.

The charge of the judge to the jury in each trial was well stated. In the case of Fitzgerald, Justice Field held that: —

A man whose mind is sound can make a will, no matter how feeble his body, but feebleness of body by age, loss of faculties, or disease is to be inquired into for the purpose of throwing light upon the condition of his mind. It is the condition of mind that you are to look at and determine, but you are to take into consideration all the facts in order to determine his mental condition. Of course the condition of a man's mind can only be determined by its manifestations, and it is for that purpose that so much evidence has been introduced, showing what Mr. Fitzgerald said, what he did, what his conduct was, in order that he may be brought before you as far as possible by the testimony; that you may see him as far as you can, and determine by his appearance, his physical condition, his conversation and conduct, what he said and what he did, what the condition of his mind was at the time he executed this instrument. The law makes a distinction between witnesses. Ordinary witnesses can only testify to facts, what they saw and observed; and you have had those before you who have told what they heard Mr. Fitzgerald say, what they saw him do, and have described his appearance as well as they can, but they have given no opinion as to his condition of mind. Some witnesses, in addition to that, are permitted to give an opinion as to whether or not a person was of sound mind at the time they saw him. The attesting witnesses to the instrument, those persons who were present and subscribed the instrument in the presence of the testator, are allowed to give an opinion as to the soundness or the unsoundness of his mind at the time. The family or attending physician is permitted to give an opinion, and experts on insan-

ity are permitted to give an opinion as to the soundness of mind of the person, and also on certain hypothetical questions, whether certain facts would prove mental disease. The weight to be given to this opinion is for you to determine, just as with the other evidence. A man may be insane or subject to certain delusions, or he may be imbecile or idiotic by reason of the decay of the mental faculties. The first you have often seen instances of in madmen; the second in cases of idiots from birth, or persons whose minds from decay have become idiotic, or from disease and old age. It is immaterial what the cause is; it is the condition of mind.

Now, how much mental capacity is necessary in law to enable a man to make a valid will? Well, in general there must be mind enough to understand, in the ordinary sense, what he was doing. [Reads from an authority presented by counsel.] He must have mind enough to understand what he is doing, to know the extent of his property, what his connections are with his relatives and other persons; his obligations and duties to them, if he has any; he must be able to comprehend the scheme of the instrument he is executing, and to understand it. He must be able to understand his relation to persons and property, and to understand the disposition of it. If he has that amount of capacity he is of sound mind within the limits of the statute. If he understands that it is his will, and is capable of understanding what the will is to be, and where the property is to go; if he has such an understanding of the business he is doing, that is capacity enough to make a will. It is impossible to describe these things with mathematical exactness. It is sometimes said that a man must be capable of attending to his usual business, but a man's business may have been large, and the demands for a successful operation of it may have been of the very highest character. He may be able to have a perfectly clear understanding of his property and estate, and a perfect understanding of their condition, but not be able to attend to the ordinary duties of his business. A man may understand and know the extent of his property, and know what disposition ought to be made of it, but he may not be able to make contracts where there are competing interests, and he might be easily over-reached, but still might understand perfectly what his property consisted of, who his relatives were, how he liked or did not like them, and what disposition he wished to make of his property. It is not capacity for doing other business, but it is the capacity to do the business itself, namely, to make a will, and the capacity to understand what he is doing, and what the effect will be. A man may also be unsound of mind by reason of disease, or insane delusions, or insane impulses. It is possible you might think a man unsound to some extent, and yet he might have a certain knowledge of the extent of his property. A man might say that the sun went around the earth, and you might think that this was an insane delusion, and yet possibly not one of you could demonstrate to him that the earth really did revolve around the sun rather than the sun around the earth as he contended, but you still might find him perfectly sane as to his connection with all persons related to him. We all know perfectly well that men differ in opinion on certain questions, and do not draw the same conclusions from the same evidence, that it does not prove the same thing to them. Therefore it is not difference of opinion or eccentricity of behavior that can be said to constitute insanity or insane delusions. It is for you to say whether these were insane delusions or merely differences of opinion, and, in order to be an insane delusion, it must go to the extent of being without rational foundation.

As the ordinary practitioner is liable to be called upon to give expert testimony in cases of mental disease it is important for him to carry in his mind what constitutes insanity under varying circumstances. The above charge makes this clear in regard to will-making.

MEDICAL NOTES.

— A correspondent of the *British Medical Journal* relates the case of a farmer, deaf for many years, in whom the membrana tympani was wholly wanting, who got a grass seed into the affected ear while loading hay. As the seed could be seen with its root end lying innermost the attendant thought that its removal by forceps would drive the barbed fibres into the integument of the canal and cause much irritation. He therefore syringed out the passage, and examination by the speculum failing to show the seed, supposed he had washed it out, but about forty-eight hours afterwards the patient discharged the greater part of the grass seed from the left nostril.

— The initial number of the *American Meteorological Journal*, published at Detroit, Mich., is at hand. This is the first American journal to be devoted to this subject. The first number contains several original communications, besides notes and translations of interest to students of meteorological science. The importance of the subject and the impetus which its study has received of late years are sufficient warrant for the appearance of a journal of meteorology.

— The *British Medical Journal* says that a parliamentary paper issued February 25, 1884, gives the number of lives lost by drowning or other accident in British merchant ships registered in the United Kingdom in the several years from 1871 to 1882 inclusive. In the twelve years the total loss of life was 38,722. of which 35,660 were crew, and 3062 passengers. The largest numbers were in 1873 and 1874, this being mainly due to the great number of passengers drowned in those years, 1167 in the former, and 572 in the latter.

NEW YORK.

— The seventy-seventh annual commencement of the College of Physicians and Surgeons took place at Steinway Hall on May 13th, when Dr. John C. Dalton, President of the college, conferred the degree of M. D. on 105 graduates. Brief addresses were made by Dr. Dalton and President Barnard, of Columbia College, and the principal address to the class was delivered by the Rev. Howard Crosby, D. D. The

Alumni Association Prize of $500, open to alumni of the college for the best essay on any subject in medicine or surgery showing original research, was awarded to Dr. Moses Allen Starr, and the usual prizes to students were announced.

— On the same date diplomas were conferred upon seven graduates of the Training School for Nurses connected with the Mount Sinai Hospital. An essay was read by one of the graduates, and addresses were made by Judge Brady and Dr. E. G. Janeway.

— The corner-stone of the New York Cancer Hospital was laid on the 17th of May by the Rev. William F. Morgan, D. D., rector of St. Thomas' Church. An address was delivered by Dr. William H. Draper, and Mr. John E. Parsons, President of the Board of Trustees, announced that the building about to be erected was the absolute gift of Mr. John Jacob Astor. He said that the fund of the institution now amounted altogether to $360,000, and that it owned twelve city lots of land in addition. The building, which is to be of pressed Philadelphia brick, will have a frontage of 120 feet on Eighth Avenue, and will extend sixty feet on One Hundred and Sixth Street. It will be after the French renaissance style of architecture, and will consist of three circular pavilions connected by a central building.

Correspondence.

INVITATION TO INSPECT THE NEW TECHNOLOGY BUILDING.

138 BOYLSTON STREET, *May* 14, 1884.

MR. EDITOR, — Will you kindly grant space in the columns of the JOURNAL for the following invitation to the physicians of Boston from the Boston Society of Arts, received this day, and greatly oblige

Yours truly, ALBERT N. BLODGETT,
Secretary of Section for Clinical Medicine, Pathology, and Hygiene, Suffolk District Medical Society.

MASSACHUSETTS INSTITUTE OF TECHNOLOGY,
BOSTON, *May* 14, 1884.

DR. A. N. BLODGETT, *Secretary:* —

Dear Sir, — I beg to inform you that at the next meeting of the Society of Arts, to be held on the evening of Thursday, May 22d, at eight P. M., Mr. S. H. Woodbridge, Instructor of Physics in the Institute, will read a paper on The Heating and Ventilation of the New Building of the Institute of Technology, and the Special Principles Involved. The paper will be illustrated by plans of the building, and a full description will be given of the apparatus, together with the results attained, which have proved in the highest degree satisfactory. The Society will, at the close of the lecture, be shown into the new building, where the apparatus will be in operation.

As this meeting will be of interest to members of the medical profession, I have the honor, in behalf of the executive committee of the Society of Arts, to tender to your Society, as a body, a most cordial invitation to be present, and should be greatly obliged to you for any suggestions which will aid me in bringing the meeting to the further attention of medical men.

Very respectfully, GEORGE F. SWAIN,
Secretary Society of Arts.

P. S. You are doubtless aware that the method adopted of warming and ventilating this building is in some degree novel, and presents many points of interest, such as justify considerable interest in the results obtained. Very truly, G. F. SWAIN.

Miscellany.

1884. MASSACHUSETTS MEDICAL SOCIETY.

ONE HUNDRED AND THIRD ANNIVERSARY.

THE annual meeting will be held at nine o'clock A. M., Wednesday, June 11, 1884, in Huntington Hall, at the Institute of Technology, Boylston Street (between Berkeley and Clarendon), Boston. The necessary arrangements have been made for the preceding day, Tuesday, June 10th.

By order of the President, FRANCIS W. GOSS,
ROXBURY, *May* 10, 1884. *Recording Secretary.*

TUESDAY, JUNE 10, 1884.

Ten o'clock A. M. The Fellows of the Society are invited to visit the Massachusetts General Hospital, in Blossom Street; the Boston City Hospital, on Harrison Avenue; the new Children's Hospital, on Huntington Avenue, near West Chester Park; and the Lying-in Hospital, 24 McLean Street.

Twelve o'clock M. At the New Harvard Medical School Building, corner of Boylston and Exeter Streets, the following communications will be presented: Methods of Instruction and Research in Physiology, with Demonstrations, by Prof. H. P. Bowditch. Modern Methods in Anatomy, with Demonstrations, by Prof. Thomas Dwight.

In Huntington Hall. Three o'clock P. M. The following paper will be read: The Plaster Posterior Splint in the Treatment of Fractures of the Leg, with its Practical Application, by G. W. Gay, M. D., of Boston.

Four o'clock P. M. The Society will hold an adjourned meeting, in accordance with the vote passed at the last annual meeting.

Invitation. The Medical Faculty of Harvard University invites the Fellows of the Society to visit the new Medical College, Boylston Street, at five o'clock P. M. The building will be exhibited, and there will be a collation at the service of the guests.

WEDNESDAY, JUNE 11, 1884.

Nine o'clock A. M. The One Hundred and Third Annual Meeting. (1.) Secretary's Record and Report. (2.) Treasurer's Report. (3.) Medical papers and communications: A Case of Chylous Deposit in the Abdomen, by F. Nickerson, M. D., of Lowell. The Pitch of the Percussion Sound, by L. Huntress, M. D., of Lowell. Sanitary Forest-Culture, by J. F. A. Adams, M. D., of Pittsfield. Weight as an Indication of the Character of Risks for Life Insurance, by J. Seaverns, M. D., of Roxbury. Communications from the Reporters of the District Societies. (4.) Introduction of Delegates. (Intermission of fifteen minutes.)

Twelve o'clock M. The Annual Discourse, by John Crowell, M. D., of Haverhill. The hall doors will remain closed during the delivery of the discourse.

One o'clock P. M. The Annual Dinner will be served in the Skating Rink, on Clarendon Street, near Boylston, to which place the Fellows, called in the order of seniority, will walk in procession.

Councilors' Meetings will be held during the ensuing year at the Medical Library, No. 19 Boylston Place, Boston, as follows: (1.) The annual meeting, at seven o'clock P. M., Tuesday, June 10th. (2.) A stated meeting, at eleven o'clock A. M., Wednesday, October 1st. (3.) A stated meeting, at eleven o'clock A. M., Wednesday, February 4, 1885.

The Annual Conference of Censors will be held at 2.30 P. M., Tuesday, June 10, 1884, at No. 19 Boylston Place, Boston.

Censors' Meetings. The Censors for Suffolk District, officiating also for the State Society, will meet in Boston, for the examination of candidates, on Thursday, June 5, 1884, and on the Thursday before the last Saturday of September and of February. But they cannot examine any candidate who is already a resident, or in practice, in any district other than Suffolk. Their meetings will be duly advertised in the *Boston Medical and Surgical Journal.*

In the other Medical Districts the Censors will hold their meetings for the examination of candidates residing in their respective districts, and none other, at the same place and on the

same day as the stated meetings of the District Societies themselves.

Memorandum. The District Medical Societies are simply Sections of the Massachusetts Medical Society, and their composition is determined by geographical considerations. They are not original and independent, but derived and *subordinate*, bodies; authorized to establish rules for their particular government, not repugnant to the By-Laws of the general Society, but "subject to the regulations of the general Society in all matters wherein the general Society shall be concerned."

REPORTED MORTALITY FOR THE WEEK ENDING MAY 10, 1884.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 2376 (no reports from Cincinnati, Buffalo, District of Columbia, Nashville, and Charleston): under five years of age, 830; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 417, consumption 343, lung diseases 315, diphtheria and croup 121, scarlet fever 65, measles 57, typhoid fever 47, diarrhœal diseases 42, whooping-cough 20, malarial fevers 19, cerebro-spinal meningitis 15, erysipelas 15, puerperal fever eight, small-pox five, typhus fever three. From *measles*, New York 21, Chicago and New Orleans 12 each, Baltimore seven, Brooklyn, St. Louis, Pittsburg, and Milwaukee one each. From *diarrhœal diseases*, New York nine, New Orleans seven, Philadelphia and Baltimore six each, Chicago five, Boston four, Brooklyn and St. Louis two each, New Haven one. From *whooping-cough*, Boston five, New York and Brooklyn four each, Chicago and Baltimore three each, St. Louis one. From *malarial fevers*, New York eight, New Orleans five, Philadelphia and Brooklyn two each, Baltimore and St. Louis one each. From *cerebro-spinal meningitis*, New York four, Philadelphia, Chicago, and New Haven two each, St. Louis, Haverhill, and Fitchburg one each. From *erysipelas*, New York seven, Brooklyn two, Philadelphia, Chicago, Baltimore, St. Louis, New Orleans, and New Haven one each. From *puerperal fever*, Philadelphia three, New York, Chicago, Boston, Baltimore, and Milwaukee one each. From *small-pox*, New Orleans four, Philadelphia one. From *typhus fever*, New York three.

Cases reported in Boston: scarlet fever 48, diphtheria 16, measles four, and typhoid fever two; in Milwaukee, scarlet fever 18, and diphtheria three.

In 100 cities and towns of Massachusetts, with an estimated population of 1,313,531 (estimated population of the State 1,955,104), the total death-rate for the week was 15.88 against 13.67 and 15.63 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending April 26th, the death-rate was 22.3. Deaths reported 3751: acute diseases of the respiratory organs (London) 327, measles 193, whooping-cough 189, scarlet fever 76, fever 40, diarrhœa 30, small-pox (London 12, Sheffield three, Liverpool two, Birmingham, Manchester, Sunderland, and Newcastle one each) 21. The death-rates ranged from 15 in Norwich to 28.4 in Leeds; Leicester 18.1; Birkenhead 18.9; London 21.6; Nottingham 21.6; Bradford 21.7; Sunderland 22; Sheffield 23.6; Birmingham 24.3; Manchester 27.1; Blackburn 27.4; Liverpool 28.1. In Edinburgh 22.2; Glasgow 29.2; Dublin 28.8.

For the week ending April 26th, in the Swiss towns, there were 40 deaths from consumption, typhoid fever 31, lung diseases 21, diarrhœal diseases 14, diphtheria and croup five, whooping-cough three, erysipelas two, puerperal fever one. The death-rates were, at Geneva 15.3; Zurich 27.6; Basle 19.4; Berne 33.3.

The meteorological record for the week ending May 10th in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM MAY 10, 1884, TO MAY 16, 1884.

WATERS, WILLIAM E., major and surgeon. Ordered to report for temporary duty to the commanding officer at Plattsburg Barracks, N. Y. Paragraph 4, S. O. 90, headquarters Department of the East, May 10, 1884.

HUBBARD, VAN BUREN, major and surgeon. Relieved from further duty at Fort Stanton, N. M., and ordered to Fort Bayard, N. M., for duty. Paragraph 3, S. O. 96, headquarters Department of the Missouri, May 12, 1884.

MOSELEY, E. B., captain and assistant surgeon. Assigned to temporary duty at Vancouver Barracks, Washington Territory. Paragraph 6, S. O. 59, headquarters Department of the Columbia, May 8, 1884.

WILCOX, TIMOTHY E., captain and assistant surgeon. Assigned to duty at Washington Barracks, D. C. Paragraph 2, S. O. 90, headquarters Department of the East, May 10, 1884.

WALES, P. G., first lieutenant and assistant surgeon. Assigned to duty at Old Fort Colville, Washington Territory, until further orders. Paragraph 3, S. O. 58, headquarters Department of the Columbia, May 7, 1884.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING MAY 17, 1884.

KINDLEBERGER, D., medical inspector, to be fleet surgeon of Pacific Station.

LEACH, PHILIP, assistant surgeon, detached from U. S. S. New Hampshire and ordered to Naval Hospital, Chelsea.

BERTOLETTE, D. N., passed assistant surgeon, detached from Naval Academy and ordered to Practice Ship Dale.

MASSACHUSETTS MEDICAL SOCIETY. ANNUAL CONFERENCE OF CENSORS.

THE annual meeting of the Censors of the Massachusetts Medical Society will be held at 19 Boylston Place on *Tuesday, June 10, 1884*, at *2.30 o'clock*. The several District Societies are earnestly requested to send a full representation by delegates to this meeting, as matters of general interest are to be presented for discussion.

ALBERT N. BLODGETT, M. D., *Secretary*.

AMERICAN NEUROLOGICAL SOCIETY.

NEW YORK, *May* 16, 1884.

DEAR SIR, — The Tenth Annual Meeting of the American Neurological Association will be held in this city June 18th, 19th, and 20th. Papers have been already promised by Drs. Putnam, Walton, and Webber, of Boston, and Drs. Seguin and Rockwell, of New York. R. W. AMIDON, *Acting Secretary*, 18 West Twenty-First Street.

OBITUARY.

DR. CHARLES H. HILDRETH, of Gloucester, died suddenly, Sunday, May 18. He was called to breakfast about eight o'clock, and, not responding, was found sitting on the bed partly dressed. He said, "I am dying," and remained unconscious until his death, at eleven o'clock the same morning. He was in his fifty-ninth year, was a son of the Rev. Hosea Hildreth, a former pastor of the First Parish Church, brother of Richard Hildreth, the historian, and the last of his family. He was a graduate of the Harvard Medical School in 1851, and practiced for a time at Deer Island. He had a large practice in Gloucester, where he has resided nearly all the years of his professional life. He was a member of the Massachusetts Medical Society since 1853. At one time he was surveyor of the port. He was a man of much public spirit, greatly interested in schools and educational interests, served many years on the school committee, and was a member of the Board at the time of his death. He leaves a widow and one son.

DIED. — In Danvers, Mass., May 1, 1884, Edgar O'Meara Fowler, M. D., M. M. S. S., aged thirty-five years.

Lectures.

LECTURE IN THE COURSE ON TOPOGRAPHICAL ANATOMY.[1]

BY THOMAS DWIGHT, M. D.,
Parkman Professor of Anatomy at the Harvard Medical School.

A NEW DEMONSTRATION OF THE AXILLA.

TO-DAY, gentlemen, we begin the region of the shoulder and axilla. In the shoulder I will call your attention to some points that have already been more or less noticed — points that may be felt. You know that we can feel at the outer side the acromion overlapping the end of the clavicle and making the prominent point. I spoke last time of the motions between these parts, and now that there has been more uncovered I may be able to show them better.

You see a long pin driven into the outer extremity of the clavicle and one into the acromion near it. You see that as I move the shoulder back there is a distinct motion between the pins. When I press upon the clavicle so as to hold it fixed and raise the arm I get some little movement between the two, but without that I get less, and in general there seems to be a very slight movement up and down. If, however, I carry the arm back and upwards at the same time, you then see a much freer movement between the two.

Below is the prominence of the humerus, which is not the head, strictly speaking, but the tuberosities. You must remember that these tuberosities are in life by no means so distinct as in the bone, because the deep groove which separates them is filled up by the long head of the biceps. The more prominent tuberosity is the outer one — the inner is placed anteriorly. You know that if we place any plane surface — a book for instance — at the side of the arm when the arm is vertical we cannot touch the edge of the shoulder-girdle if the head of the bone is in place. It is said that the groove between the tuberosities can be felt, but I think pretty unsatisfactorily, in the living subject. By deep pressure at the inner side of the head you can feel the coracoid process. On this side, where the dissection of the last time has been carried rather farther, I can show you from the base of the coracoid process these two parts of the coraco-clavicular ligament, the trapezoid and the conoid. This one outer and anterior is the trapezoid; the other posterior and internal, the conoid. Between them is a small synovial bursa. As this anterior one runs upward and forward it is easy to understand that this is the one which limits forward motion of the clavicle, because as the clavicle goes forward it carries its upper attachment away from the other one. The converse is true of the conoid. Looking now at the back, before we go any farther, I will call your attention first to the great thickness of the skin, which depends, not upon the subcutaneous tissue, as in some parts, but upon the thickness of the derm proper. Here it is that Dr. Warren discovered his fat canals. You can easily see how exceedingly thick that is. You can contrast it with the delicate skin on the front. Beneath is subcutaneous tissue which has been removed. Here you see the deep fascia which binds down the parts in the region of the shoulder very closely. By this line you make out the posterior border of the deltoid, and you see that this fascia which I cut at its posterior edge is continued over the outer surface of the muscle that I am cutting, which of course is the infraspinatus. The fascia splits into one, the denser, layer going over the deltoid, and into another following the infraspinatus. The supraspinatus also has a pretty well-marked fascia, and this accounts for the pain felt in these parts when they are distended.

The deltoid seen on this side is, perhaps, a larger muscle than we are at first inclined to imagine, coming from the outer third of the clavicle and about all the spine of the scapula. It is made up of very coarse fibres, and these are arranged so as to run for the most part towards a tendon which before its insertion is made up of three or four radiating bands of fibrous tissue. In the middle part of its origin, that is, from the acromion, the muscle arises by means of a number of fibrous bands, from either side of which there go off muscular fibres that are again inserted into the divisions of the final tendon so that the extent of origin is very much increased.

It presents a general resemblance in the coarseness of its fibres to the gluteus maximus. This muscle raises the arm, but, as I have shown you on the living subject, this movement is by no means so simple as we have supposed. It has been generally taught us, or at least we have been led to infer, that when the arm is raised outwards it is brought to a horizontal position by the deltoid and then the movement is continued by the muscles moving the scapula. In point of fact, as Mr. Cathcart, of Edinburgh, has shown, the scapula takes a part in the early stages, and even in the latest there is motion between the arm and the shoulder girdle. This is an instance of the advantage of the live model. The supraspinatus, which is supplied by the same nerve as the deltoid, helps also in raising the arm — it is not merely an external rotator.

I have here a demonstration of the axilla, and incidentally one of the shoulder, that I hit upon some years ago, and as far as I know it is new, that is, inasmuch as it concerns the axilla.

The deltoid having been laid bare, a V-shaped cut is made over the outer aspect of the shoulder and the flap turned up. The capsule is then divided close to the humerus, and that bone sawn through at the lower end of the axilla. The parts in the bottom of this cut are slightly cleaned, the bone then fastened on to the shaft, and the flap replaced. We now turn up the deltoid and show the humerus. If the dissection had been made before you so that the parts should be perfectly fresh, you would see a glairy space over the bone between the periosteum and the areolar tissue of the under side of the deltoid. You get some hints of it in the glistening appearance of the lower fibres, which show a large synovial bursa which is continued under the acromion. (See how the acromion hangs over the joint.) This bursa is one of many in this region.

You see here the head of the bone, or, more accurately, you see its greater tuberosity — the one with three facets. Here is a groove which I can follow now very distinctly, in which rests the long tendon of the biceps. Almost directly in front I feel the lesser tuberosity, and as I put my finger around I feel the smooth surface of the head of the bone. This long head of the biceps going in this deep groove of course does a great deal towards holding the bone firmly. Let us consider incidentally the action of the muscle. The biceps bends the arm, and therefore we infer illogically that if the arm is not bent the biceps

[1] Delivered March 27, 1884. Reported verbatim by Messrs. Pomeroy and Smith of the Harvard Medical School, and revised.

is doing nothing. Imagine the arm thrown forward as in fencing or boxing, and although certain muscles of the chest throw the upper arm forward and the triceps extends the elbow so that the arm is not in the least bent, nevertheless the biceps is in firm contraction, and one object of that is that this long head being made tense keeps the arm perfectly firm in this position, so that it cannot rotate nor "wabble" to one side or the other. Here is the capsule, and in that are the insertions of the supra and infraspinati, the teres minor, and the subscapularis. It is well to point out how very high up these extend over the head of the bone. The external rotators are closely united to the capsular ligament, but can be separated by careful dissection. Not so this one which can be seen on the inside, going to the lesser, internal tuberosity, the subscapularis. It is perhaps an exaggeration to say that it perforates the capsule, but it is so intimately connected with it that if you pass around from the inside of the synovial membrane you see unmistakable signs of its tendon, and there is beside it a bursa which very frequently communicates with the joint. That being opened we see here the cavity of the joint, and in this case you see something that is not seen every day. It is, no doubt, abnormal, but still it is something that may occur. It probably occurs more frequently than we are aware of. I refer to the way in which the capsule is inserted into one side of the glenoid cavity. This shallow cavity is deepened, as you know, by the glenoid ligament, which is a band of fibro-cartilage continuous above with the long head of the biceps and passing around the joint. From the outside of that we have the outer part of the capsule arising, but, according to some authorities, on the inside the capsule arises not from the edge of this but outside of it, that is, away from the middle of the joint. Sometimes it rises a quarter of an inch or more, or, according to Morris, it may be as far out as the base of the coracoid process, so that all this part to the inner side of the head and neck of the scapula is really inside the cavity of the joint, and that is precisely what occurs here. The capsule on the inner side has not been destroyed, and I put my finger here upon the synovial membrane and carry it far along to the inner side of the glenoid cavity and carry it up to the base of the coracoid process, and am still in the undisturbed synovial cavity.

I would call your attention once more to the front of the humerus. You see a part of the long head of the biceps, which was cut both above and below, left in this gutter, where it is surrounded by a prolongation of the synovial membrane, as you see when I remove the tendon.

Now we pass down to the consideration of the axilla. The axilla, which I will show you presently on the other side in the usual classical way, is generally described as a pyramidal cavity, bounded in front by the pectoral muscles, behind by the scapula or the subscapularis lining it, and the borders of the latissimus and teres major, on the inside by the chest covered by the serratus anticus, and on the outside by the humerus with the coraco-brachialis and biceps. When handsomely dissected in that way it is a pyramidal cavity without any base to the pyramid, and consequently you have no guide to the relative distances from the surface of those structures which you see passing through it like telegraph wires. It is a handsome dissection, but the view is false anatomically.

It occurred to me that this might be obviated, and a view given which would be useful in some ways if we were to approach it from the other side in the manner described. In this case the bone has been divided a little above the lower border of the axilla, the cut running through the middle of the insertions of the latissimus and teres major. That being done we pull out the head of the bone, and now we look at the axilla from above. We see no pyramidal space; we see simply the reverse of the skin and fascia from this side, and here I have between my thumb and finger the bundle of arteries, veins, and nerves. The skin is closely adherent to the fascia so that it cannot sag out of place. At the last lecture I pointed out the continuity of the fascia with that of the neck, and mentioned how a process of it has been termed the suspensory ligament of the axilla.

Now let me return to the classical description of the axilla.[1]

We now return to the view from behind. Showing you once more the capsule that has been cut and reflected, I now pull out here from the front of the scapula the subscapular muscle, and you see distinctly how the vessels and nerves rest upon its anterior surface. Lower down I show you the cut ends of the latissimus and teres major. And here in this bundle of vessels and nerves one white band is particularly evident, and that is, of course, one of the posterior branches of the plexus, the great musculo-spiral. From it is given off a nerve which runs inward to accompany the ulnar nerve, and which has the peculiarity of running down in its sheath without any interchange of fibres until it gets near the elbow. Here is an artery which is shown remarkably well, namely, the posterior circumflex, and beside it the circumflex nerve. They come out above the long or scapular head of the triceps so as to curve around the neck of the humerus to appear at the outer side. Here they are quite undisturbed until they were cut after they had made the circuit and reached the posterior surface.

The veins can be seen very well, and by pushing them apart we may see the artery, and to the inner side I get the ulnar nerve. The internal cutaneous is farther in front, and I doubt if I see it in this dissection, but here, very prettily shown, are one or two little nerves at the under side of the axilla, close above the fascia, branches, no doubt, of the intercosto-humeral nerve. Deep in is the artery. You may see it as I press upon the skin below and bring it out. And pushing these veins aside we come to a nerve lying on its outer and anterior surface, that is the median. Without any particular trouble another nerve can be made out at the outer side which plunges at once into the muscle, that is the external cutaneous. Pressing this a little aside you see a strong fascia, the axillary fascia, and in it can be seen clear white fibres which seem to strengthen it in a transverse direction. I press this upwards with my fingers, and have once more the whole bundle of vessels and nerves between my thumb and finger, and as I put up the arm you can see just where they are at the lower part of the axilla. They lie somewhat nearer the anterior than the posterior fold, and are felt along the line of the biceps and coraco-brachialis. The merit of this demonstration consists in showing the floor of the axilla, and above these important structures with their relations almost undisturbed.

[1] See text-books.

It seems to me that possibly it would be well for me now to cut through the joint between the acromion and the clavicle, then passing the knife underneath, above the coracoid process, to divide the coraco-clavicular ligaments, and then the muscles attached to the coracoid process. I next turn the scapula back, and am able to give you a freer view of the same thing, though the relations are no longer undisturbed. Here you see one very large vein and here another which lie on the two sides of the artery, and rather behind it, so much so that I am inclined to suspect that there is a third, the real axillary, in front, and that these are two large venæ comites. The arrangement is an irregular one. You can see here more clearly the first nerve, the musculo-spiral, and cutting now these veins you see below them here the artery, and pressing it aside we see the median nerve close to it. Here is the ulnar farther to the inside; here some branches of the intercosto-humeral; the internal cutaneous here; and, indeed, here is the lesser internal cutaneous. It is worth while now to look up from this space towards the neck, and see the areolar tissue, which is the fascia, plus fat, which follows these vessels. That can be seen in these plates from Braune's frozen sections.

I have one other experiment to show to-day, and that is to exhibit the action of the coraco-clavicular ligaments. The first thing that you notice on cutting them on the other shoulder is the falling of the arm. That is, of course, natural, — that the coracoid should fall down when its attachments are severed, — but I fail to see that the amount of movement in a horizontal plane is materially changed. In a vertical plane it is distinctly increased, for you remember we found before it was exceedingly slight, now it is much better marked.

Address.

EXTRACTS FROM THE ADDRESS AT THE ANNUAL MEETING OF THE PENNSYLVANIA STATE MEDICAL SOCIETY.[1]

BY HENRY H. SMITH, A. M., M. D. U. P., PRESIDENT.

SHALL PENNSYLVANIA HAVE A STATE BOARD OF HEALTH?

The creation by *our* Legislature of a State Board of Health, whose duty it shall be to supervise and recommend such measures of drainage, water supply, etc., as will promote health and ward off disease, is a question that has often been discussed in this Society. During the past ten years this object has been strongly urged by many of our most valuable and energetic members, who have freely given their time and money to secure a proper law for this purpose.

Although they have repeatedly failed in convincing our law-makers of the importance of such a bill for the public good, may we not hope that, like the mythical Antæus, they will receive new strength each time they are cast down on the legislative grounds? The cause of these repeated failures is variously explained; but the main reason is that suggested by our Committee on Medical Legislation, namely, the ignorance of our people in regard to the importance and utility of such a law.

[1] Concluded from page 483.

The organization by this Society of the proposed "Pennsylvania Association to secure a State Board of Health" will probably do much towards creating judicious public sentiment. Let each county society make arrangements to hold several meetings of citizens before the next session of the Legislature, at which brief papers may be read by its members, and speeches made by the local lawyers, divines, and prominent candidates for public office; or let special speakers be invited from other sections to address a meeting for such a purpose, and the public will soon become aware of the necessity of a State Board of Health to protect their own interests. Let each county society urge the introduction into their schools of instruction in the elements of human physiology, and each child will soon introduce the subject of the lesson to each family and knowledge will be extended. Let health tracts be widely distributed through every avenue of trade or travel. Let the masses be made to understand by these means, and especially by public meetings, that it is *their* welfare that is sought, and not that of the medical profession, and *they* will influence the candidates for office. The Latin proverb says, "Docendo disces" — by teaching others you are taught; and as he who teaches also learns, he will probably be the more impressed with the importance of legislative action for a State Board of Health.

Teach every one the importance of a Board to regulate such general sanitary measures as the heating and ventilating of large buildings, especially factories, public halls, and schools; the proper means of removing excreta; the prevention of the spread of small-pox, scarlet fever, diphtheria, whooping-cough, etc., so that children and others residing in infected localities shall not be allowed to attend funerals, come to schools, or otherwise be brought in contact with those who are well.

Let there be an inspection and regulation of vaccine farms, now that competition is rendering bovine virus in some instances dangerous. Let there be such an inspection of food and medicines, particularly the "artificial foods" of infants, as is given every sailor and soldier by our government laboratory at Washington. Let the farmer especially be made to realize that it would be the duty of a State Board of Health to protect his stock against the extension of hoof and mouth disease, pleuro-pneumonia, glanders, or hog and chicken cholera. Let every one be taught that the object of such a law is the appointment by the Governor, with the sanction of the Legislature, of such a capable board, not all physicians, but containing lawyers, sanitary engineers, and other citizens, as may be proved by the nominations of organized scientific institutions or local boards of health to be capable of executing this important trust. In the interval that elapses before the next session of our Legislature the mere circulation of such information would do much to create a sound popular sentiment on this question, especially if our collegiate faculties and school teachers are invited to aid us in instructing all in the laws of hygiene and the necessity of enforcing them by legal statutes.

The wording of such a bill as might become a proper law is a matter demanding very careful consideration. In drawing it, as has been well shown by Dr. Foster Pratt, of Michigan,[2] "experience teaches the importance of careful determining in advance what and

[2] MS. of Dr. Pratt.

how much power you can induce your Legislature to grant."

"The practical question," says Dr. Pratt, "in the beginning of such attempted legislation, is not so much what you would like to have as what you can get. It is easy to defeat a measure by asking too much." Experience also shows, according to Dr. Pratt, "that you are sure to defeat your movement by asking for legislation that recognizes only *regular* physicians."

"Those of us who are sincerely and unselfishly desirous of promoting the sanitary interests of the public cannot too soon, nor too fully, recognize one fundamental fact, that under our form of government a *State medicine*, direct or implied, is as impossible as a *State religion*, and that all denominations of practice, like all denominations of religious belief, are and must be equalbefore the law."

The Judicial Council of the American Medical Association have also decided "that in questions of legislation and governmental policy, on which every physician as well as citizen must be allowed full liberty of opinion and expression, a conference with homœopathic or irregular practitioners is not a consultation at the bedside as contemplated in the Code of Ethics."[1]

Dr. Pratt's experience and success in obtaining legislation on this question, and his study of the subject in various States, make his opinion very valuable, and I commend it to your careful consideration. . . .

THE METHOD OF INFLICTING CAPITAL PUNISHMENT.

It may not be inappropriate in connection with the subject of State Medicine also to call attention to the propriety of memorializing the Legislature to modify the present mode of capital punishment and make it correspond with the scientific progress of the age.

Without discussing the necessity of such punishment we may justly urge, that as its main object is the removal from society of those whose lives are detrimental to its best interests, this should be accomplished in the least painful manner, and it does seem as if death by means of electricity should at present receive due consideration.

It has frequently happened in the incautious handling of wires connected with electric lights, etc., that instantaneous loss of life has ensued, and it is not surprising that the inventive genius of our people should have already suggested the application of electricity to executions.

I feel, therefore, that I advance the cause of humanity when I direct attention to this subject with a view of obtaining legislative sanction.

The history of the invention is as follows[2]: —

"Mr. H. B. Sheridan, of New York, applied last year for a patent on what he termed 'An improved device for executing criminals condemned to death,' and proposed to assign the right to use his invention to the United States Government.

"His apparatus, he says, causes instantaneous death, without pain to the criminal and without disfiguring his body.

"It consists of an ordinary arm-chair, with legs containing some substance that will *insulate* the body of the chair from the floor. The arms end in two brass knobs, on which the hands of the criminal will rest, and the chair has a foot-rest in which is fitted a brass plate. The back of the chair is as high as a man's shoulders. At the top is a small knob with a hole for a peg. The *positive* wire of a dynamo-electric machine running up the back of the chair ends in the knob. The *negative* wire runs to a resistance coil under the chair and thence to a brass plate in the foot-rest. Another *positive* wire runs to one of the brass knobs on the arms of the chair, and a second *negative* wire to the other knob. These wires can be connected with a dynamo-machine, miles away, by conducting wires.

"The chair may be used in two different ways, as the two sets of wires are not operated together.

"If the foot-rest wire is used, some previous preparation is needed, and a small silken collar is fitted tightly on the neck of the criminal. This has on the inside, at the back, a small brass button which fits closely against the spinal process. This is connected with a small silk cable which hangs down loosely and ends in a brass peg. This collar being put on the criminal in his cell, he is then brought out in his bare feet and seated in the chair. Straps fasten his arms to the arms of the chair, and his legs to the chair legs. The brass peg of the silk cable is inserted in the hole on the brass knob at the back of the chair, and is there held by a screw. The bare feet of the criminal rest on the brass plate of the foot-rest, and the circuit would now be complete were it not that the positive wire is broken at a short distance from the chair, but connection can be at once established by turning a switch or pressing a button. When this is done the full charge of electricity enters the criminal's body at the spinal cord and passes out at his feet, the resistance coil which it meets under the chair increasing its force and preventing it from injuring the dynamo-machine on its return; the criminal being killed instantaneously and without pain, as the electricity acts much more rapidly than the nerves of sensation.

"The second method of using the chair is to discharge the current into the palms of the hands through the large brass knobs. In this case no collar is needed, and the criminal need not be barefooted. In either case all the wires and apparatus excepting the small collar would be out of sight, and the criminal would see nothing but an ordinary chair. The sheriff can signal the executioner to turn the switch or he can press a button on the floor, and in a second all would be over."

Mr. Sheridan says he does not wish to make money out of this machine, but has invented it solely in the interest of humanity, and thinks there is no possibility of its failing to do its work quickly and well. Should his suggestion recommend itself to the approval of the Society, it remains for you to urge the passage of such a law as will justify its use as a substitute for hanging. . . .

In reverting to the work done by our Society, and comparing the present with the former condition of the profession, it is instructive to note, that whilst the great aim of the Society is yet the improved treatment of disease, and the elevation of the standard required for a medical diploma, our opinion of what is most feasible in the latter is the fruit "of the association of kindred spirits in the development of one great purpose."

SOME OF THE DANGERS AND DISADVANTAGES OF ANÆSTHESIA.[1]

BY DAVID W. CHEEVER, M. D.,

Professor of Surgery in Harvard University, Surgeon to the Boston City Hospital.

THE form of anæsthesia considered in this paper is that produced by the inhalation of sulphuric ether. Unconsciousness of pain in surgical operations is the greatest boon bestowed on man.

What victim of surgery who, under ether, sinks into a calm and dreamless sleep during which his abdomen can be cut open, his bowels taken out, handled, and replaced, his nerves cut, his veins or arteries tied, and his skin sewed up, and who wakes so absolutely oblivious as to ask "Are you not ready to begin?" but concedes with gratitude on realizing the result that this is the greatest discovery ever made for the happiness of mankind? Speed of locomotion, electric transmission of speech, the preservation of the printed thought of all the centuries seem at such a moment small in comparison.

Any one about to suffer the agony of an amputation, who was told that if he would take a considerable risk in breathing ether he should feel nothing, would choose the risk and the oblivion.

But the second great quality of this Letheon is that it is almost free from danger. Deaths from ether are rare. Having used it for twenty-six years I have never seen one. The largest statistics give one death in 23,204 cases.

It would take a long list to exhaust the benefits ether has conferred on surgery. The domain of justifiable and beneficent surgery has been greatly enlarged by anæsthesia. The patient seeks an operation with but little dread. He is operated on earlier and better. Many conservative operations are now done which could not be thought of before ether. Many examinations and diagnoses can be made with it which could not be made without it. Many simulators and malingerers are detected under its potent spell.

These vast advantages and this wonted safety have masked the disadvantages and obscured the dangers which may arise.

Ether can kill, and there are operations which can be better done without it.

Hitherto all that I have said is trite and axiomatic. It is the object of this communication to point out what is the danger and what the disadvantage in breathing sulphuric ether.

(1.) The danger in breathing ether is chiefly from impeded or failing respiration. The heart outlasts the lungs. Suffocation, or coma at the breathing centre, are the causes of death. Temporary paralysis of the palatine muscles causes the stertor or snoring respiration, and the falling back of the *tongue* carries with it the epiglottis, and closes the larynx. When this condition threatens the operator opens the mouth, and perhaps draws forward the tongue. When, however, he sees the tip of the tongue out to the incisor teeth he thinks it safe, but in this he is mistaken. The tongue in this position still blocks the entrance of air on account of the falling of the palate, and it is only when the tongue is forcibly drawn out of the mouth that the air-passage is opened, and suffocation averted. The larynx can also be opened by placing from behind the two thumbs under the angles of the lower jaw and pressing forwards. The muscles of mastication being relaxed the jaw subluxates over the *eminentia articularis* or, rather, on to it, and carries forwards the tongue, and with it the epiglottis, and thus opens the larynx, the mouth being already open.[2]

(2.) In some persons, and we cannot foresee in whom, the mucous membrane of the throat and air-passages is very sensitive to the irritating fumes of ether. This sensibility first shows itself in croupy respiration, a spasmodic stridor followed by an incessant dry cough. Letting in more air relieves the spasm of the glottis, and the narcotism of more profound etherization soon quiets the tickling cough. In many persons there soon follows a new peril from a great *secretion of frothy mucus*. The mouth, pharynx, and nares bubble with fluid, and soon the same oversecretion pours out in the bronchi, fills the air-passages, and finally approaches a capillary bronchitis. Slow lividity ensues, the arteries spout venous blood, and the patient is on the verge of suffocation, drowned in his own secretions. This is a very tiresome complication. Etherization has to be entirely suspended for a considerable time.

(3.) Tetanic symptoms are often annoying, and if not relieved by appropriate treatment become dangerous. Obstinate pronation of the fore-arm and wrist, inversion of the thumbs, opisthotonos, boring by boring the head back in the pillow, these are evidences of suffocation, and are relieved by removing the ether, and allowing of a few inspirations of air. Once I saw this condition in a child terminate in a convulsion, which, however, was not fatal. A most dangerous complication is *tetanic setting of the inspiratory muscles of the chest.* No air enters; respiration with the diaphragm fails to fill the lungs, and the patient dies as in true tetanus. I once saw this condition in a middle-aged man. It came on instantly without warning. The mouth and larynx were free, the tongue out, the position good. Respiration absolutely ceased, but the pulse continued. Artificial respiration, forcibly, by the Sylvester method, restored the breathing, and the chest again inspired. In this case there was no stridor at the glottis. The operation was continued and completed without ether, and the patient recovered well. This condition must not be confounded with that where the diaphragm is seen laboriously pumping on a collapsed lung, the glottis being closed by the tongue or by spasm.

(4.) *Simple exhaustion* is another source of danger in anæsthesia. Death may occur from slowly failing respiration, so gradual as not to attract notice. Such a case of threatened death from pure debility occurred to me where a feeble woman insisted on an immediate operation for the removal of a cystic tumor of the breast. Sulphuric ether was inhaled quietly, and complete anæsthesia produced, without spasm, frothy secretion, or lividity. The breathing was especially quiet, but both diaphragm and intercostals were working, the mouth open, and the tongue out. After several imperfect sighing respirations a deathly pallor spread over the face, ears, and neck, the pupils dilated, the

[1] A paper read before the American Surgical Association, April 30, 1884.

[2] The relaxation of the muscles in complete anæsthesia being similar to that in death the manœuvres to open the larynx were illustrated by the reader on a wet preparation of the head and neck of the *cadaver*, of which appropriate sections had been made by Dr. Thomas Dwight, professor of anatomy in Harvard University.

jaw fell, the breathing ceased. The pulse continued beating very feebly. The aspect was that of death. Artificial respiration and stimulation restored life. The tumor was removed without ether, and the patient evinced no consciousness until the sutures were being passed. She made a slow but good recovery. A momentary inattention on the part of the surgeon and assistant would have insured a fatal result. A second case like the above occurred to me in operating for a tumor of the jaw. The fauces were free of blood and mucus; there was no obstruction, but breathing gradually ceased. This patient was restored by artificial respiration, and did well. The latter case was being operated on in a chair, and faintness may have contributed to the result, but the former case was lying in an easy position on her side in bed. In neither case was there evidence of pulmonary or cardiac disease.

(5.) *Disease of the heart* may cause death during the inhalation of ether. Well marked valvular disease, pericarditis and effusion, or a fatty and feeble heart, may contribute to a fatal result, and yet I have repeatedly etherized patients with valvular disease with safety by using caution, and giving them plenty of time. Sulphuric ether is a stimulant to the circulation, and if given slowly, well mixed with air, and not pushed either to lividity or exhaustion, may be given safely in many cases of heart disease.

A middle-aged man was brought into the hospital with retention and urinary extravasation. Immediate incisions and perineal section were imperative. He was etherized, and as I was about to cut breathing ceased. The pulse stopped also. Artificial respiration and stimulation revived him. The operation was done without ether. He lived ten days. At the autopsy I found extensive and old valvular disease of the heart.

(6.) *Apoplexy*, sanguineous or serous, may follow the coma of etherization in the old, or in drunkards. Atheromatous vessels may give way under the great congestion produced by full anæsthesia; and the "wet brain" of alcoholism may succeed the stupor of ether.

Having reviewed the dangers, we now pass to the disadvantages of anæsthesia.

Does etherization diminish shock?

Primary shock it does lessen. It removes apprehension, and it annuls pain. But it does not remove the secondary shock which follows an operation. Etherization is primarily stimulating, and acts like alcohol in enforcing the heart and filling the pulse.

Secondarily, or long continued, it is exhausting. Long etherization prostrates the patient. A frequent pulse, lowered temperature, drenching sweats, and nausea are the sequences of an anæsthesia which lasts more than from half an hour to one hour.

(7.) One of the marked *disadvantages* of anæsthesia is that it decoys the *operator* into *delay* and *slowness* in his work.

Before ether the skill of the surgeon was estimated by his celerity. A good operator was a brilliant and a quick one. The agonies of the patient enforced haste. Every means was used to shorten his suffering. Now all is changed, — largely to the surgeon's comfort, largely to his increased care and prudence, and as largely to delay, to deliberation over the steps of an operation, and to a too cautious and sometimes puttering execution. The patient may benefit by greater skill and by more conservatism; but he suffers from prolonged exposure, tedious narcotism, greater secondary hock.

(8.) Drunkards and steady drinkers succumb slowly to the narcotism of ether. They pass through a long period of excitement and delirium before they get the sleep; they have an equally long and violent delirium on coming out. They are subject during etherization to *persistent* and *recurrent tremors*, which delay an operation or jeopardize its safe execution. It is frequently not until the surgeon has finished that they become quiet and narcotized.

(9.) *Vomiting* and *lasting nausea* are among the disadvantages of etherization. The larger proportion of patients vomit during anæsthesia or after it, or both. This is especially disastrous in abdominal sections, in operations for hernia, and in section of the cornea and iris.

Vomiting during the operation may expel the vitreous humor. Vomiting after an operation I have seen extrude a strangulated intestine anew into the hernial sac. Vomiting after an operation equally is liable to disturb the stump of an ovariotomy and bruise peritoneal and omental adhesions, or, in an amputation, to burst the congealed mouths of small vessels, and lead to secondary hæmorrhage under the flaps of a stump. Nausea may last two days, and may turn the scale against successful rallying from secondary shock. We know of no agent to arrest it.

(10.) *Intoxication and delirium* on coming out of ether are especially injurious after a simple, or worse still, a compound fracture, has been set. Except in a child, or to settle a diagnosis, the setting of broken bones is better done without ether. In nervous women the delirium assumes the form called hysterical. I have seen it last for twenty-four hours.

The following operations are better done without anæsthesia: —

Extraction of cataract, already spoken of.

Tracheotomy for disease.

Paracentesis thoracis.

In tracheotomy for croup and diphtheria the little sufferer is already partially narcotized with carbonic acid. The cut frightens him no more than the ether would. The incisions through the skin comprise most of the pain. On the other hand, when etherized he often stops breathing, and the operation has to be done precipitately and not so well. It is absolutely essential, if you open the trachea in a child without anæsthetics, that you have abundant, cool, and competent assistants.

Tapping the chest and pumping off the pleural effusion has frequently been perilous, and sometimes fatal, with an anæsthetic. It is a safe operation without it.

There is no reasonable doubt that complete anæsthesia during parturition leads to tardy contraction of the uterus after labor, and hence increases the risk of flooding.

Deaths from inhaling sulphuric ether are rare. It is a noteworthy fact that most of them occur during operations on the rectum, perinæum, or in the vagina. The reason is not far to seek. The surgeon is too far removed from the anæsthetic to notice the mouth, the tongue, the respiration, the chest, the diaphragm. An incompetent assistant or a nurse holds the ether sponge, and the patient may die before her peril is discovered. The operator should watch the levator ani muscle, which moves with the diaphragm. This may be called perineal or pelvic respiration.

What are the essentials for giving ether safely?

An empty stomach.
A loose neck.
A free abdomen; no corsets or skirt bands.
Removal of artificial teeth.
An easy, semi-recumbent position.
A sponge wrapped in towels for the ether.
A gag, and forceps for the tongue.

When stertor occurs the patient should be tipped forward, the cheek opened with two fingers, the tongue drawn out, the fauces swabbed. To *insure* safety the surgeon should hear every respiration of the patient.

Anæsthesia from sulphuric ether is of two forms:—

(1.) Primary anæsthesia, which is a moment of confusion coming on after a very few inspirations. At this moment a felon can be opened without pain, and the patient wake at once.

(2.) Comatose anæsthesia, for prolonged operations. Ether *may* be given almost indefinitely. To relieve the hopeless agony of tetanus I have had it administered for twenty-four hours.

If you would avoid asphyxia, nausea, and headache, and be *safe*, use only the best and the purest anhydrous sulphuric ether.

Reports of Societies.

THE AMERICAN LARYNGOLOGICAL ASSOCIATION.

SIXTH ANNUAL CONGRESS, HELD IN THE CITY OF NEW YORK MAY 12, 13, AND 14, 1884.

SECOND DAY. MORNING SESSION.

DR. F. H. HOOPER read a paper entitled

A RARE FORM OF TUMOR (CAVERNOUS PAPILLOMA) OF THE VOCAL BAND.

On account of the ease with which the growth described was removed, as well as its rarity and pathological interest, the case, he thought, was deserving of the attention of the Association. The patient, who was a clergyman thirty-two years age, was first seen by Dr. F. I. Knight, November 22, 1882. At that time he refused any operative interference. In 1883 he was referred to Dr. Hooper. He said he had always been healthy, and that in September, 1882, he suffered from a cold, with hoarseness. At the end of three weeks the cold left him, but the hoarseness had remained ever since, and had been so troublesome that he feared he would be obliged to give up preaching. Apart from the hoarseness and a tendency to "scrape" the throat there was no symptom referable to the larynx. A laryngoscopic examination showed the presence of a small, nodular, sessile growth on the anterior part of the left vocal band, of about the size of a number seven shot. It was thought to have some of the characteristics of a cystic tumor, but the diagnosis was very doubtful. On the occasion of the patient's second visit, with a view rather of testing the tolerance of the larynx than the idea of actually removing the growth, Dr. Hooper introduced a Fauvel forceps, but on withdrawing the instrument and placing it in a glass of water it was seen to have been detached, and adhered to one of the blades. The hæmorrhage was insignificant, and a subsequent examination with the laryngoscope showed that the entire mass had come away. The tumor was submitted to Dr. W. W. Gannett, who pronounced it cavernous papilloma. Its cavity was filled with red blood corpuscles, and he expressed the opinion that the growth had consisted of cavernous tissue from the start. The voice of the patient was at once restored to its natural tone, and there had been no return whatever of the trouble since. He had recently held special services daily for six weeks, and notwithstanding this unusual strain upon his voice had remained in good condition all the time. The only case resembling this which had thus far been reported, so far as Dr. Hooper knew, was one published by Fauvel. Drawings representing sections of the growth were presented for inspection.

[1] Continued from page 495.

DR. CARL SEILER said that he had met with a case very similar, with the exception that the epithelial structure was not as far developed as in Dr. Hooper's case, the growth being more of an angioma. The patient was a student of elocution, and all that he complained of was hoarseness.

DR. MORRIS J. ASCH, of New York, read a paper entitled

A CASE OF ECCHONDROSIS OF THE LARYNX.

Having mentioned that cartilaginous tumors of the larynx were rare, and referred to the literature of the subject, he said that there were only two cases on record in which the true character of the growth had been recognized during life. The patient in whom this occurred was forty-two years of age and an amateur vocalist of some ability. He complained of constant irritation of the throat, and also of continued hoarseness. Before operating Dr. Asch made a correct diagnosis of the character of the tumor, which sprang from the inner surface of the thyroid cartilage, on account of its hardness. He removed it with a modification of Stoerk's guillotine, the ring being made of well-tempered steel, with a cutting edge on its upper border. The growth was pronounced by Dr. George L. Peabody, pathologist to the New York Hospital, to be a cartilaginous tumor undergoing calcareous degeneration. There had been no return of the trouble, and since the operation the patient had gained two notes in his vocal register. The case was of interest as showing, *first*, that tumors of this character came under the care of the laryngologist not only for diagnosis but for cure, and, *second*, that they could be cured by endo-laryngological methods.

The paper was discussed by Drs. Cohen, Seiler, and Langmaid. The latter expressed the opinion that the increase in the vocal register after the operation was due, *first*, to the removal of the irritation, and, *secondly*, to the moral effect on the patient by the relief thus afforded him, and in this Dr. Asch concurred.

DR. W. C. JARVIS, of New York, read a paper on

A NEW METHOD FOR THE REMOVAL OF LARYNGEAL GROWTHS.

The agent which he employed for this purpose was chromic acid, and the form of growth for the destruction of which it was specially adapted was papilloma. As, according to Mackenzie, sixty-seven out of one hundred tumors of the larynx were papillomata, and Cohen had found forty-eight out of sixty-six tumors of this character, it would be seen, he said, that its field was quite an extensive one. He was aware that there was a deep prejudice in the minds of laryngologists against

this agent; but he felt convinced that it was not deserved, since it had arisen from its abuse and not its proper use. He did not wish, however, to exclude the forceps and the snare. The case in which he had first employed it was a very bad one, a large papilloma filling up almost the entire larynx, reducing the voice to a discordant whisper, and causing dangerous spasm and dyspnœa. In nine days, on five of which no applications were made, the voice was restored to its natural tone, and in nineteen days the patient was pronounced cured, and the treatment discontinued. Having explained the action of the remedy and the method of application, Dr. Jarvis summed up his views as follows: —

(1.) Trioxide of chromium, or chromic acid, locally applied, has a self-limited action.

(2.) It is a safe and reliable means for the removal of large and small soft laryngeal tumors.

(3.) It also has the effect of preventing their return.

(4.) It is best employed fused on the point of a probe.

(5.) An instrument to act as a protector and guide may be used with it. (This was exhibited by Dr. Jarvis, and consisted of a tube provided with a trigger and a spring, the force of which could be accurately regulated. Its objects were, *first*, to prevent the acid from coming in contact with the tissues before reaching the growth to be removed, and, *secondly*, to surprise the larynx.)

(6.) Its use is not necessarily attended with pain or spasm.

(7.) It offers a substitute for tracheotomy and thyrotomy in certain cases where these measures are ordinarily judged necessary.

The paper was discussed by Drs. Cohen, Roe, Seiler, Ingals, and Major, and the discussion brought to a close by Dr. Jarvis, after which a number of

NEW INSTRUMENTS

were presented. Among these were a nasal speculum devised by Dr. J. N. Mackenzie, a tonsillotome with three blades, and a uvulatome by Dr. C. E. Sajons, and an apparatus for artificial feeding by Dr. D. B. Delavan.

SECOND DAY. AFTERNOON SESSION.

DR. D. BRYSON DELAVAN, of New York, read a paper entitled

PERMANENT UNILATERAL PARALYSIS OF LARYNGEAL ABDUCTORS, FOLLOWING CEREBRAL HÆMORRHAGE. UNIQUE CASE.

He had been able to find no recorded case of this character, and the only reference to the condition met with which he had seen in medical literature was in Nothnagel's article on cerebral hæmorrhage in Ziemssen's Cyclopædia, where he simply remarked that unilateral paralyses of the vocal cords (as a result of such hæmorrhage) were exceedingly rare.[1] The paralysis had occurred in connection with paraplegia, the result of cerebral hæmorrhage in a patient sixty-nine years old, and had now lasted since 1877; though all the other paralytic trouble had long since disappeared. Dr. Delavan said he had no theory to advance in connection with its ætiology.

DR. F. I. KNIGHT reported a case, which he said was very pertinent to Dr. Delavan's, where a patient, as the only injury from falling down stairs and striking his head, suffered from unilateral paralysis of the abductors. There was probably some lesion either of the nerve or at the nerve-centre.

DR. R. P. LINCOLN, of New York, read a paper describing a case of

STRICTURE OF THE ŒSOPHAGUS.

The stricture was due to medullary cancer, which involved the larynx, trachea, œsophagus, and cervical glands, and death was due to implication of the cardiac branches of the vagi nerves. No sounds or bougies could be used without exciting inflammation; and on only one occasion was a bulb-pointed catheter passed without producing this result. This was but a very short time before the patient's death.

In the discussion, which was participated in by Drs. Roe, Knight, Donaldson, Daly, and Ingals, Dr. Roe suggested that Krishaber's method of leaving an œsophageal tube *in situ* might perhaps have been tried, and Dr. Daly said he thought that there might perhaps have been a chance for gastrotomy.

DR. LINCOLN closed the discussion. In reply to Dr. Roe's criticism he said that it was to be borne in mind that any attempt at interference with the œsophagus, at least any sufficient to pass a sound, was always followed by great inflammatory reaction. Moreover, there was a prompt improvement that attended the soothing treatment at first instituted which seemed to justify its continuance. In regard to Dr. Daly's suggestion he wished to say, that while the statistics of operations so far reported gave but little encouragement for adopting the method, in any case, certainly the sequel in this case showed that it would have been useless; the cause of death having been pointed out to have been due to implication by the disease of the cardiac branches of the vagi nerves.

DR. E. FLETCHER INGALS, of Chicago, read a paper on

TRACHEAL STENOSIS,

in which he related the histories of three cases which had come under his observation during the past year, all of which were of syphilitic origin. In one tracheotomy was performed. He advocated large doses of iodide of potassium as of special value in this affection.

The paper was discussed by Drs. DeBlois, Shurley, Langmaid, and Delavan, most of whom mentioned cases that they had seen. The President remarked that the opinion generally expressed by the Fellows seemed to be in favor of the iodide. For himself he preferred mercurial inunctions, as he believed the iodide a dangerous remedy in this affection, on account of its tendency to produce œdema. In the treatment of syphilis in general, even in the later stages, he had gradually come to use the iodide less and less, and to rely more and more fully upon mercury.

DR. INGALS replied that he believed it to be a fact that the iodide was not nearly as likely to produce coryza, œdema, etc., in large doses as in small ones. Thus, he knew of a physician who suffered from iodic coryza if he took five grains of it, but not if he took ten grains or more.

THIRD DAY. MORNING SESSION.

DR. T. A. DEBLOIS, of Boston, read a paper, in which he gave the histories of two

[1] American edition, vol. xii., p. 116.

CASES OF BUCCAL TUBERCULOSIS,

both of which speedily proved fatal. He thought the affection sufficiently rare to deserve mention whenever it was met with, either where the tubercular deposit first showed itself in the mouth, or where, after manifesting its presence in other parts of the body, it finally extended itself into that region. He did not believe there was any good reason to doubt that tubercles always existed in the lungs before they appeared either in the pharynx or the larynx, and he was fully prepared to admit the same in regard to buccal tuberculosis.

The paper was discussed by Drs. Langmaid and Bosworth.

DR. C. E. SAJOUS, of Philadelphia, read a paper on

HAY FEVER AND ITS SUCCESSFUL TREATMENT,

in which he set forth the following propositions: —

(1.) That there was an idiosyncrasy existing in certain individuals to become influenced by certain emanations or irritating substances.

(2.) That the idiosyncrasy was accompanied by a chronic hyperæsthesia of that part of the nasal mucous membrane covering the anterior and middle turbinated bones, the middle meatus, the floor of the nose, and that part of the septum between the limits of the olfactory membrane.

(3.) That organic alteration of these parts annulled that hyperæsthesia, preventing, at the same time, what symptoms the patient might be liable to in case of an access.

(4.) That any destructive agent would induce that organic alteration, but the galvano-cautery was by far the best, being painless, effective, and devoid of all danger when used in practiced hands.

He said that until after he had finished the paper he had not been aware of Dr. Roe's articles on the ætiology and treatment of hay fever.

A long discussion followed, in which Drs. Shurley, Roe, Mackenzie, Robinson, and S. Johnston took part. The President then expressed the opinion that in every case of hay fever there were three essential elements: a neurosis, a structural change in the nasal cavities, and a special sensitiveness to dust, pollen, or other source of irritation. If any one of these factors were removed the case would undoubtedly be cured, and it did not make the slightest difference which one of the elements was done away with, the result would be the same. The discussion was brought to a close by Dr. Sajous.

DR. E. L. SHURLEY, of Detroit, read a paper on

THE COMPARATIVE VALUE OF THE GALVANO-CAUTERY IN DISEASES OF THE NASAL AND PHARYNGEAL CAVITIES,

in which he gave his preference to this method of destroying tissue, as a rule, over mechanical instruments and chemical agents. The tendency of the present day, he thought, was to destroy too much tissue, and he therefore advised that as little as possible should be injured or destroyed, and that as narrow a tract as would suffice should be cut through the neoplasm to be removed. The paper was discussed by Drs. Jarvis, Sajous, Roe, Mackenzie, and Bosworth, the President remarking that there could be no doubt that American laryngologists were now beginning to do much better work than their brethren in Europe. Dr. Shurley closed the discussion.

DR. BEVERLEY ROBINSON, of New York, read a paper entitled

A CONTRIBUTION TO THE STUDY OF ADENOID VEGETATIONS AT THE VAULT OF THE PHARYNX,

which was mainly derived from his own experience. In it he stated that he had found this to be a much more rare affection than was commonly supposed, and that it was not nearly so frequently associated with aural disease as many authorities stated. He had never yet met with a single instance in which pressure of the growth over the Eustachian tubes gave rise to deafness. He also took exception to follicular pharyngitis being considered of an adenoid character, although he acknowledged that the two affections were not infrequently associated. In the treatment he had employed the method of Meyer, of Copenhagen, to some extent. Also the Thomas uterine curette, followed by applications of nitrate of silver or the galvano-cautery, and, in the case of pedunculated growths, the snare.

In the discussion which followed, which was participated in by Drs. Langmaid, Mackenzie, Major, Roe, Asch, and Jarvis, it seemed to be the prevalent opinion that disease of the ear was perhaps more frequently associated with adenoid vegetations than Dr. Robinson believed. In closing the discussion the latter remarked that the most important point which he wished to bring out in his paper was that the galvano-cautery, the snare, and other violent measures were really of no use in one half of the cases of nose and throat disease in which they were employed, and that not infrequently they did harm.

The last paper of the session was read by DR. LOUIS ELSBERG, of New York, on

SPASM OF THE GLOTTIS.

This he defined to be the spasmodic contraction of one or all of the laryngeal muscles. The spasm might be simple or complicated (with similar contraction of other muscles), unilateral or bilateral (the latter being almost universally met with), and might occur in the domain of either the superior or inferior laryngeal nerves. Again, the spasm might be expiratory (including the phonatory), inspiratory, or deglutitory.

In considering the ætiology, he said that the most important predisposing cause was morbidly increased irritability of the nervous system. Age was also a very important factor, the affection occurring most frequently between the ages of four months and two years. It was a mistake, however, to regard it as exclusively a disease of childhood. Male children were more subject to it than females, but in adult life it was more frequently met with in females than males. Heredity, as well as the general condition, had considerable bearing in the causation. Children badly nourished, and living in unhealthy and badly-ventilated apartments, were especially liable to it, and rachitical and hydrocephalic children were frequently attacked with it. It often came on at the time of weaning, and, as a rule, it was more common in hand-fed than in nursing infants. Enlargement of the thyroid had formerly been supposed to be the only cause of it, but in reality this was not a cause at all, though it was frequently present in cases in which it occurred. Among the other causes he mentioned were hysteria, injuries from food getting into the larynx, catarrhal inflammation of the

respiratory mucous membrane, gastric disturbances, enlargement of the tonsils, and emotions like anger and fright.

The symptoms varied according to the set of muscles affected. In abductor spasm there was insufficient closing of the rima glottidis. There were several forms of adductor spasm: —

(1.) Deglutitory. The attacks were usually short, with complete immunity from dysphagia in the interval, but in one case which he had seen there was complete spasm of all the adductors for a week, so that the patient was actually threatened with starvation.

(2.) Inspiratory. This was characterized by closure of the rima glottidis, and might be mistaken for paralysis, though this might coexist.

(3.) Simple phonatory. In this there were no symptoms until the patient attempted to use the voice, which would be choked in sound. If phonatory efforts were persisted in, however, dyspnœa was liable to result.

(4.) Simple expiratory. Here the attack came on if the patient attempted to whisper as well as to speak or sing. It had been known to come on in the acts of blowing out a candle, of coughing, and of laughing.

(5.) Complicated expiratory. This was the form sometimes called "curious cough." In regard to its mode it might be paroxysmal or continued. In the continued the hacks were not as severe as the cough, and they observed a certain rhythm. Chorea was sometimes noticed in connection with it, and this was the kind of spasm that had given rise to the name of "laryngeal chorea." Such terms as "laryngeal chorea" and "laryngeal epilepsy," however, he said, ought never to have been employed, and he trusted that they would soon be dropped forever from medical literature. The acoustic characteristics of this variety were very peculiar, and the sound might resemble barking, quacking, lowing, or crowing, while it was often very loud.

(6.) Complicated inspiratory. This was the most common and dangerous, and was the form ordinarily known as laryngismus stridulus. The graphic description of it by Morell Mackenzie, in his work, gave a true and striking picture of its characteristics. In speaking of the prognosis Dr. Elsberg quoted from Mackenzie the statement that the longer the interval was between the attacks the greater was the chance of recovery.

The treatment, he said, often required great promptitude, sometimes operative skill, and always good judgment. The ordinary means for relaxing spasm, he thought, would occur to all, and for lack of time he would not dwell upon them. It was often necessary to thrust the finger into the throat to see if the epiglottis was impacted, and catheterization of the trachea was sometimes required. This he preferred to tracheotomy.

After the paper had been briefly discussed by Drs. Ingals, Jarvis, and Roe, and Dr. Elsberg had replied, the officers for the ensuing year were elected as follows: President, Dr. E. L. Shurley, of Detroit; first Vice-President, Dr. S. Hartman, of Baltimore; second Vice-President, Dr. William H. Daly, of Pittsburg; Secretary and Treasurer, Dr. D. B. Delavan, of New York; Librarian, Dr. T. R. French, of Brooklyn; and Members of the Council, Drs. F. H. Bosworth, of New York, and F. Donaldson, of Baltimore.

The time and place of the next meeting were left to the decision of the Council.

PROCEEDINGS OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.[1]

ALBERT N. BLODGETT, M. D., SECRETARY.

DR. T. A. DEBLOIS read a paper upon

TONSILLITIS.

DR. J. W. FARLOW opened the discussion upon this subject as follows: I agree with Dr. DeBlois in thinking that it is not possible to draw so sharp a line as is generally done between follicular, parenchymatous, and phlegmonous tonsillitis. When the parenchyma is affected the follicles are also liable to be, giving rise to the secretion, more or less of which we find in most cases. Of two cases which begin and continue alike for several days, one may remain an ordinary case of tonsillitis while the other goes on to the formation of an abscess.

The difficulty of knowing whether diphtheria or some other disease is to follow what looks at first like simple tonsillitis has been well described by the reader, as also the need of "hedging" in communicating the diagnosis to the friends of the patient.

In cases seen early where there is much fever I am in the habit of ordering a Dover's powder or aconite, to be followed by a saline in the morning. I have never satisfied myself that I had benefited a case by the use of guaiac or chlorate of potash.

I have never found astringent gargles of more use than very hot water. I direct the patient to fill his mouth at frequent intervals with hot alkalized water and hold it for several minutes. He is then to let the water run out by holding his head over a basin. This serves to remove the thick, tenacious secretion of which patients always complain, and which they find great difficulty in expectorating. Gargling is always a painful process in such cases.

I find relief from scarification, especially when the uvula is œdematous. When the presence of pus is probable, a deep incision, whether pus is found or not, makes the patient much more comfortable.

DR. PRINCE thought it was a very interesting paper, and agreed with the reader in what he had said regarding the efficacy of the different varieties of treatment that were in use. For himself, he took a different view of the pathology of the affection from the reader, and believed in the *constitutional nature of the disease.* This was a point of considerable importance from the stand-point of treatment. He did not mean to say that every case of follicular tonsillitis was the expression of a constitutional fever. On the contrary, as in inflammations in other parts of the body, there was a local as well as a constitutional form.

Specialists who principally have to do with cases in dispensary and office practice meet with the former variety, while general practitioners see the constitutional form. The latter class of patients are usually too ill to leave their beds, much less the house, and are not found in out-patient departments of hospitals, or at least not till the disease has run its course. In this way the difference of opinion regarding the pathology of the affection can be explained. He thought that specialists were more inclined to see in follicular tonsillitis only a local affection, while general practitioners more commonly thought it of constitutional origin.

[1] Concluded from page 472.

His own views of the constitutional nature of the affection are based upon various facts; among others, the severity of the constitutional symptoms observed. Even when associated with insignificant local inflammation, it is not uncommon to see high fever, great prostration, severe backache, sweating, headache, anorexia, and stupor, followed by protracted convalescence, though the local trouble was so slight as hardly to induce the patient to use the gargles, etc., prescribed.

As a result of his studies he has found: —

(1.) With slight local inflammation high fever and severe constitutional disturbance, and *vice versa*.

(2.) Slight local inflammation and slight increase of temperature combined with severe constitutional symptoms, showing that the latter were not dependent upon the fever.

As "hospital sore throat" the disease was very common amongst internes and nurses in hospitals. He had found as a result of his inquiries that sixty-three per cent. of the internes in the Boston City Hospital had the disease, and that fifty-nine per cent. of the nurses in the hospital at the time the inquiry was made had already had it. Many more would probably have it before their term of service was finished. Under these conditions the disease was usually very severe, more so than could be accounted for on the theory of a simple local inflammation.

The disease also occurred in epidemics, of which several had been reported. He had recorded two in a paper on this subject read before the Society about two years ago. In the epidemic form it was certainly constitutional.

The reader had said that he himself was liable to the disease and was frequently affected, but Dr. Prince believed that while this might be true of simple catarrhal sore throat, such as is met with in dispensary practice, the form to which he referred he believed usually occurred but once in the same individual.

In regard to treatment of this form, he had found the best to be painting the throat frequently, every hour or two, with co. tinct. benzoin. The tonsils must be thoroughly covered each time so as to leave a deposit of the yellow gum upon the surface. This always relieved the pain, and enabled the patient to swallow with comparative comfort. He had not yet met with a case which was not benefited by this, though of course it could not be inferred that the remedy would never fail. An ice bag around the neck gave great relief to the head symptoms, while sponging the body with alcohol and water did the same for the backache. He also gave Dover's powders at night and sometimes during the day. The constitutional symptoms in his experience called for more active treatment than the local manifestations.

Dr. Cobb mentioned a case of tonsillitis occurring in a Swedish girl, accompanied with the appearances of abscess. On puncture, a small amount of pus was liberated, but the entire quantity was not evacuated. Within a week the girl was admitted to the City Hospital with scarlet fever. The question was asked if such cases were frequent.

Dr. DeBlois stated that one such case had recently come to his notice. The case was one of follicular tonsillitis with much depression and exhaustion of strength. The prognosis was of a grave character from the threatening nature of the symptoms, which led to the apprehension of some other more serious disease, and a few days later the patient suddenly expired while being brought down stairs to be taken to the City Hospital.

The following particulars in this interesting case were communicated by Dr. George G. Hayward, the physician attached to the Dispensary District in which the patient lived.

DIPHTHERIA WITH COMPLICATIONS.

Patient, male, nineteen years of age, laborer, single, born in Ireland, had only been in this country a few months, was a strongly built man, of temperate habits. He first came under my charge December 12, 1883, and was treated at that time for dyspepsia and a heavy cold, from which he soon recovered, and after a few days went about his work again. I next saw him February 2, 1884, and learned that the day previous he had been to the Boston Dispensary Throat Department, where he had been treated, and that diphtheria had been suspected. At this time there was high fever. Temperature 105° F., rapid pulse, tongue heavily coated, and all the soft parts covered with a distinct membrane, some of which was with difficulty removed. On further examination the body was found covered more or less thickly with a fine rose-colored eruption, more especially marked upon the lower part of the abdomen and thighs (where he was actually the color of a boiled lobster).

Diagnosis, was made of diphtheria with scarlatina. I afterwards learned that there had been scarlet fever in the house a few weeks previous.

Treatment, was Dover's powder at night, hot gargles, or rather douches, steamed flannels externally, changed often, and replaced by dry ones, steam inhalations, and as much steam as possible kept in the room, carbolic sprinkled about the floor. The mouth was swabbed out three times daily with hot water applications.

Diet. Milk, beef tea, ice. Stimulants in milk occasionally. Nourishment was taken fairly well until the last day, so much so that it was only given by the mouth.

February 3d. Temperature 104° F. About the same condition, breathing well, however; treatment continued.

February 4th. Temperature 103.5° F. Seemed somewhat improved and brighter; more membrane removed, and it was stated that some more had been coughed up during the night.

February 5th. Was called early on account of alarming symptoms. Temperature 104° F. Face flushed; skin dull color; pulse slow and feeble, but breathing was good; voice very feeble. There was no indication for tracheotomy, which I had supposed might be required from what was told me of the symptoms.

The trouble seemed to be rather failure of the heart's action than anything else.

Dr. Kingman saw the case with me in consultation, agreeing with me as to diagnosis, and we decided it was best to send the patient *at once* to the hospital.

The heart was examined at this time as it had been several times previously, and no organic trouble could be detected.

Digitalis was at this time given, followed later by carbonate of ammonia, and the patient was ordered to the hospital. On leaving him he seemed considerably improved, and roused himself enough to shake hands and ask me to come and see him.

Brandy in milk was ordered before starting.

Instead of taking him at once he was left three

hours, and while being carried down stairs, having just reached the lower landing, he fell and died soon after. This would seem to indicate failure of the heart, and had it not often been previously examined, I should have been inclined to suspect organic disease.

The case seems to me doubly interesting, —

(1.) As a rare combination of disease.

(2.) As to the cause of death.

DR. FARLOW asked if any member had been able to observe any beneficial result from the employment of chlorate of potassium in tonsillitis.

In answer to Dr. Farlow's question as to the curative effect of chlorate of potassium in tonsillitis, DR. V. Y. BOWDITCH said that he had no faith in its curative effect, but believed that hot gargles containing it often gave great relief both from the grateful sense of warmth and from the fact that it seems to cleanse the mouth from the thick secretions and disagreeable taste which are present. He also testified to the efficiency of the guaiac lozenges in relieving soreness of the throat, and recommended those of the London Hospital Pharmacopœia as being pleasant to the taste.

DR. DISBROW asked Dr. DeBlois if there was any means of aborting the disease in its early stage. Speaking from his own experience, having suffered for many years with attacks of tonsillitis, he found by painting the tonsils with tinct. iodine comp. two or three times a day in its early stage, he prevented the formation of pus and cut short the disease. He had also found a strong solution of nitrate of silver useful, and he had used the comp. tinct. guaiacum, but had not found any benefit from it. He had used, to hasten the formation of pus, an old domestic gargle composed of vinegar, water, sugar, and capsicum, in conjunction with hot poultices externally. In follicular tonsillitis he had found painting with tinct. iron very useful. In regard to the guaiacum troches, they have been very useful in a case of irritative cough after other means had failed.

DR. DEBLOIS thought that patients often swallow with less difficulty after the use of chlorate of potash, and this is certainly of benefit as far as it goes. If we can remove the pain and discomfort the inflammation will in many cases take care of itself. Scarification is often of service in the same way. Troches containing guaiacum are also often of service in tonsillitis.

DR. HARLOW stated that in the opinion of an eminent Boston physician, now dead, guaiacum never did anybody any good except the apothecary.

Adjourned at 10.05 o'clock.

PHILADELPHIA CLINICAL SOCIETY.

G. BELTON MASSEY, M. D., REPORTING SECRETARY.

STATED meeting, April 25, 1884. The President, DR. HENRY BEATES, JR., in the chair.

DR. HANNAH T. CROASDALE reported a case of

VESICO-VAGINAL FISTULA WITH INVERTED BLADDER.

The record which is brought to your notice this evening is that of a case which perhaps is possessed of more than ordinary interest from two circumstances: first, from the enormous size of the opening in the septum, and secondly, from the fact that from the orifice a bright round body protruded, which was discovered to be the bladder inverted. The patient, M. F., aged forty-seven, was admitted to the Woman's Hospital October 11, 1881. She was married at the age of twenty-five and had one child stillborn. The labor was instrumental, and incontinence of urine occurred soon after it, thirty years ago.

For this trouble and great discomfort the woman never sought relief, and speaks only of her present suffering having begun one year before admission. This suffering had been so intense that she had been obliged to keep her bed for that length of time. The journey from her home had been made on a bed. Her appearance was deplorable. She had constant pain in the lower part of the abdomen; bowels were constipated, appetite poor, face anxious, and she was constantly distressed lest the bed or her clothing be moved and thereby her sufferings be increased. It seemed almost hopeless to expect to do anything for the poor woman's relief, so disturbed was her health from her desperate condition.

Nausea and vomiting were almost constantly present. Her pulse on the day following that of her admission was 65; temperature 99° F.; and respiration 26. The quantity of urine in twenty-four hours could not be ascertained. The color was pale yellow; specific gravity 1000; reaction alkaline, and there was a trace of albumen. After ineffectual attempts she was finally etherized and thoroughly examined October 29th.

The tumor which was so exquisitely sensitive was the inverted bladder, and the exposed mucous membrane was greatly inflamed and bled readily on being touched. The openings into both ureters could be distinctly seen. The mass was grasped and by gentle taxis was reduced and retained by the slight support afforded by one of Skene's glass stylets made to pass through the urethra with the distal extremity resting upon the upper edge of the fistulous opening. A vaginal glass plug was introduced into the vagina to aid in supporting the bladder. The inflamed condition of the parts forbade any further procedure at this time.

On the 30th of November she was again etherized and placed in the lithotomy position, and the edge of the fistula, which was about five centimetres in diameter, was carefully pared, beveled from the vesical margin giving a broad surface on the vaginal septum, and twelve sutures of silver were introduced. It was necessary, before closing the fistula, to liberate adhesive bands at either angle, and then the margins of the opening were closed by the sutures and secured by perforated shot. A self-retaining catheter was introduced, to which was attached a piece of rubber tubing for conveying the urine to the urinal. The patient was then placed in bed and one sixth grain morph. sulph. given hypodermatically; she was ordered lime water and milk every two hours.

The following day, December 2d, there was much vesical tenesmus, which gradually subsided, and nothing especially worthy of note occurred until December 7th, when the sutures were removed. Union was not perfect at either angle, and in the centre there was a small orifice which admitted the passage of urine.

January 6th the patient was again etherized, the edges of the three minute openings freshened, and fine silver wire suture introduced. The central and right openings promptly closed after this second operation, but the left, just at the site of the ureter, admitted the passage of a Snelling's probe.

Then January 20th, February 3d, and March 28th I operated, hoping to close this minute orifice which

still remained, and which still allowed of the passage of urine when the bladder was filled. Not one of these efforts was followed by any better success. These attempts were always made with a probe carried through the urethra into the opening in the ureter in order to prevent wounding or closing the latter.

It was now thought best to send the patient home and encourage her coming again in the autumn, as her stay had already been much prolonged beyond the usual time for keeping patients in the hospital, and she was discharged May 8, 1882, quite content on her part with the result of the many operations — six in all. After several months, however, the urine ceased to pass through this opening, probably from the contraction of cicatricial tissue.

I find many contributions to the surgical literature for the relief of vesico-vaginal fistula, but nowhere have I found any record of a case of an inverted bladder through the fistulous orifice.

THIRTY-FIFTH ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

Friday, May 9th. Fourth Day.

The meeting being called to order by the President, Dr. J. C. Dalton, chairman of

the committee on experimental medicine,

offered resolutions supplementary of those previously reported to the following effect: That the Association desires to express its earnest conviction that experimentation on animals is most useful for the promotion of medical science, and should be intrusted only to members of the medical profession. That the committee be continued and empowered to fill vacancies. Adopted.

resolution concerning nominations of journal trustees.

Dr. Grissom, of North Carolina, then offered a motion, which was carried, that in future nominations to vacancies on the Boards of Trustees of the Association's *Journal* be made by the Committee on Nominations.

reports of committees.

The Committee on the President's Address reported through its chairman, Dr. N. S. Davis, that several members had left the city; that no declarations or explanations concerning the Code should be made without careful consideration; that the committee be continued with instructions to report at the next meeting. This was adopted, and the President was added to the committee.

The Committee on Nominations then reported the names of W. W. Allport, of Illinois, as chairman, and Edward C. Briggs, of Massachusetts, as secretary of the Section on Oral and Dental Surgery.

international medical congress.

A permanent committee on the invitation to the International Medical Congress was appointed with the following members: Drs. H. F. Campbell, President-elect, Hays, Sayre, Christopher Johnson, Engelmann, J. M. Browne, Billings.

medical education.

Dr. Von Klein, of Ohio, gave notice of a proposed amendment to the By-laws, as stated in two resolutions: —

Resolved, That no person who shall hereafter graduate from a college where an educational test is not a prerequisite to admission shall be a delegate to the Association.

Resolved, That all delegates shall present as a part of their credentials a certificate, from the county or State society they represent, showing from what college and when they graduated, excepting delegates from the army and navy.

resolutions and amendments.

Dr. Pratt, of Michigan, proposed an amendment that each Section nominate its own chairman and secretary. He also made a motion, which was carried, that a pamphlet containing the minutes of the Association, with its Constitution and By-laws, be prepared by the publishers of the *Journal* for distribution among members at the next meeting.

A resolution was adopted urging upon Congress the importance of providing for a Museum of Hygiene.

Resolutions by Dr. Pratt requesting Congress to legislate for the prevention of the immigration of the insane and pauper classes to this country, which had been ruled out of order earlier in the day, were brought up again and voted.

Dr. Seiler, of Philadelphia, offered an amendment to the Constitution dividing the Section of which he was secretary into (1) Ophthalmology, (2) Laryngology and Rhinology, Otology.

The Treasurer's annual report showed a balance on hand of $2212, and it was voted to continue the annual dues at $5.

Resolutions were offered and adopted urging Congress to provide for the publication of a new edition at cost of all the volumes of the Medical and Surgical History of the War of the Rebellion, and others urging more stringent laws against pleuro-pneumonia.

A resolution, offered by Dr. Von Klein, of Ohio, to abolish the opening of sessions with prayer, was rejected.

A resolution protesting against the indorsement by members over their signatures of mineral waters and pharmaceutical preparations was carried.

Resolutions from the West Philadelphia Medical Society in earnest support of the Code of Ethics, and resolutions from the St. Louis Medical Society condemning professional advertisement through medical colleges, were all referred to the Judicial Council.

Dr. A. L. Gihon, of the United States Army, brought forward a motion, which was carried, that a committee be appointed to further the erection in that city of a monument to Dr. Benjamin Rush.

A large number of delegates were appointed to the International Medical Congress; and, after the passage of votes of thanks to all individuals, institutions, and corporations which had extended hospitalities and courtesies to the Association, and of a vote of thanks to the presiding officer, the thirty-fifth annual meeting of the Association was adjourned.

— *The Archives of Pediatrics*, a medical monthly devoted to the diseases of infants and children, will henceforth be issued from the New York office of John E. Potter & Co., publishers.

Recent Literature.

History of the Discovery of the Circulation of the Blood. By HENRY C. CHAPMAN, M. D. Philadelphia: P. Blakiston, Son & Co. 1884. 8vo. 56 pages.

In these days of restless research and experiment, when a new and specific bacterium may be had almost for the asking, and the highest culture is brought, as it were, to the very doors of the bacillus, it is a pleasure to record evidence of an interest in the history of any portion of medical knowledge. Such is to be found in this lecture by Professor Chapman, which relates the gradual development of our acquaintance with one branch of physiology.

The tercentenary of Harvey's birth (April 1, 1578) naturally called attention to his relations to this discovery. Not only in England was a fresh interest in this subject awakened; the Italians were astir to advocate the claims of their countrymen to a share of the merit. This national rivalry has provoked not a little acrimonious discussion, but the field has been freed of much prejudicial rubbish, and the true relations of Harvey to this question are becoming clearer.

Until very recently it was a tremendous heresy to doubt his claims to the completest originality as a discoverer and his superiority as a man. Now our estimate of him has been much modified and corrected, and although the idol have lost something of its glory, the honor due to others has been more wisely distributed. A portion of the literature of this dispute is in Italian, some, and not the least valuable, is in German, of which that contributed by Tollin is the most important; even the English portion is not too readily accessible to the American reader, and many will be grateful to Dr. Chapman that he has been led to put the tale into a handy form in English, and one convenient for the student. In this he has succeeded well, and the fair-minded reader, even though unfamiliar with the history of the discussion, will probably agree with him in his judgment that the discovery of the circulation of the blood belongs to no one man or age, but that many men have builded thereon, sometimes perhaps better than they knew, and that even in our times important additions are made.

Dr. Chapman fortifies his position with numerous references to the authorities, and considerable quotations from the works of those who have a claim upon the discovery. He has refrained from any too detailed account of Harvey, and the curious (and as some believe misguided) English enthusiasm for him. In this he has doubtless done wisely, but a fuller bibliography of this portion of the subject would have been very acceptable. The printer, however, has made a sad mess of many of the quotations, touching, apparently, no language to adorn it. Such as we have been able to verify present numerous and curious slips of the type-setter, which need not be noted here. It is, perhaps, well to remark that the reference to Haeser (p. 13) is to the first volume of the third edition, and that Berengar de Carpi is the more common form, not Berenger; Mundini (p. 13), Guntherus (p. 25), and Rumi (p. 38) are of course *lapsus oculi* for Mundinus, Guintherus, and Ruini. These are slight oversights, easily corrected in the work on Physiology which Professor Chapman is preparing, and of which this lecture will form a chapter. In the allusion to Erasistratus (p. 11) the hope is incidentally awakened that other subjects as well will receive historical treatment in the larger work. Should this prove to be the case we shall have a book of unusual interest and value.

Handbook of Vertebrate Dissection. By H. NEWELL MARTIN, D. Sc., etc., and W. A. MOALE, M. D. Part III. How to Dissect a Rodent. New York: Macmillan & Co. 1884.

This is the third part of the eminently practical work now appearing. It is not a text-book of comparative anatomy, nor precisely what we call a "dissector," though partaking of the character of one. In short, it teaches the student how to dissect a rat, which is chosen as a representative of the class of mammalia, and special attention is accordingly given to the characteristics of the class rather than to those of the genus or species, or to minute points of structure. This is the plan, and it only remains for us to say that the work strikes us as excellent.

A Course of Instruction in Zoötomy (Vertebrata). By T. JEFFERY PARKER, B. Sc. London, Professor of Biology in the University of Otago, New Zealand. With Seventy-four Illustrations. London: Macmillan & Co. 1884.

This book reaches us together with that just noticed, and is very similar to it in method, but is of a wider scope, giving directions for the study of the lamprey, the skate, the cod, the lizard, the pigeon, and the rabbit. The choice depends somewhat on the prevalence of these animals in New Zealand. The author has been demonstrator to Mr. Huxley, and acknowledges his assistance in looking over parts of the work written in England. We have nothing but praise for the execution of the work.

Legal Medicine. By CHARLES MEYMOTT TIDY, M. B. F. C. S., etc. Part II. Philadelphia: Henry C. Lea's Son & Co. 1884.

The promise and hope held forth in the first volume of this work, that the author would give to his readers, as the full result of his labors, a complete treatise on legal medicine, is not disappointed in this the second part of the series. The same care is manifested in the composition, the same remarkable industry in the critical review of the medico-legal literature of the world is illustrated. To many students of forensic medicine this second volume may, indeed, prove more attractive than its predecessor on account of the range and nature of the subjects discussed, and because those subjects are of more practical interest, as the following necessarily brief analysis will show.

In Chapter I., under the general head of Legitimacy and Paternity, are discussed the topics of impotence and sterility in the male and the female, hermaphrodism, the medico-legal relations of utero-gestation, and the signs of maturity in the newly-born child.

In the second chapter the medico-legal aspects of pregnancy are studied; the signs of pregnancy and of recent delivery, in the living and the dead, are given,

including a full discussion of the vexed questions relating to the value of the *corpus luteum* as evidence of conception.

The third chapter is devoted to abortion and fœticide, followed by a full and discriminating treatment of the subject of rape and its related topic, the signs of virginity.

The legal and physiological difficulties connected with "live birth," with a consideration of the evidence by which the medical jurist proves the child to have been dead at birth, are fully elaborated in the next chapter, and serve to introduce the reader to the study of infanticide.

The last five chapters are given to the discussion of asphyxia in its general relations, and to special examples of that process as they are illustrated in death by drowning, by hanging, by strangulation, and by suffocation.

This bare outline will serve simply to indicate the variety and scope of the medico-legal topics treated in this volume. It can furnish no hint of the attractiveness with which they are presented, or of the intelligence, good judgment, and erudition, which the author has displayed in this encyclopædic work. As in the first volume, so in this, the plan of attaching to each chapter a copious appendix of illustrative cases drawn from all sources, and referred to in the text by means of parenthetical numerals, is a source of great convenience; the cases thus cited are of the latest as well as of older date, and in themselves constitute one of the most valuable features of the treatise. Another useful innovation is the grouping, at the end of each section, of specific directions for the practical application of the rules and principles previously discussed.

Many quotations might be made to illustrate the conservative and judicial tone which pervades the author's writings. In his preface to the work he expresses a sentiment which every medical expert would do well to include among his golden texts: "For the medical jurist, whose object should be the interests of justice, to hesitate where science is positive is as unjustifiable as for him to speak without reserve on those details of our science where the limits of exact scientific knowledge are undefined. There is a scientific certainty which only the coward treats as uncertainty, and there is an uncertainty which only the boldness of ignorance ignores." Of this suggestive and thoughtful statement the author makes just application in his volumes, and his pages are therefore remarkably free from misleading dogmatism.

Medical Annals of Baltimore from 1608 to 1880, including Events, Men, and Literature. By John R. Quinan, M. D. Baltimore. 1884.

The Medical Annals of Baltimore contain an interesting record of medical sayings and doings from 1608 to 1880, and a short biography of the practitioners of Baltimore, whose labors in the cause of suffering humanity endeared them to their contemporaries. We do not know of so complete a work in reference to the other cities of this country. Dr. F. H. Brown has given us an account of the members of the Massachusetts Medical Society, and we learn when they entered the profession, and have a list of their publications. Dr. Quinan tells us of those who have lived as well as of those now living, and of their works, giving a list of those who have served their country in the army and navy, and tells us of all medical institutions and boards of health. We congratulate the Medico-Chirurgical Society of Maryland on having so complete a history of members of the medical profession practicing in Baltimore, so full an account of medical publications during so long a period. The profession in Baltimore cannot be accused of neglecting to put in writing their experience and their opinions, and exhibit commendable industry in writing as in practicing. The younger members of the profession in that city have a powerful stimulus to well-doing in so many examples of patient and faithful work.

The Field of Disease. A Book of Preventive Medicine. By B. W. Richardson, M. D., etc., etc. Philadelphia: Henry C. Lea's Son & Co. 1884.

Whatever may be said in praise of the beneficence of the healing art unquestionably applies with far more than double force to the beneficence of the preventive art, or more properly, science, against disease. As soon as men allowed themselves to doubt if diseases were a portion of the necessary sufferings of humanity the first step was taken toward prevention, and that was not very long ago. Preventive medicine, in so far as it exists to-day, is, with the exception of isolated movements, such as the introduction of vaccination against small-pox, the growth of the last thirty years. Its basis rests upon a rational and reliable system of registration and of vital statistics, the development of which, in England, dates back less than fifty years. It was only last April that the name of William Farr, the founder of this system of registration, to a great degree the model for those of other countries, passed through the office of the registrar of deaths, and was added to the sixty million names whose registration had passed under this official supervision.

Just as in curative medicine there is the theory and the practice, the first step being to elucidate the nature and the locality of the disease, and the second to select, on rational principles, the appropriate remedies, so in preventive medicine we must first have vital statistics to show us when, where, and how men are sick and die before we can undertake to remove the causes of sickness and death except in so far as this may be accomplished by a fortunate empiricism.

The practitioner of to-day is looked to by his regular clients quite as much to shield them from the approach of disease as to relieve them from its consequences, and as larger demands are and will be made upon the State to prevent causes of sickness, so a gradually increasing number of medically educated men will devote themselves exclusively to that part of State medicine which falls under the head of hygiene.

In the present work the author investigates first the nature, secondly the causes, and afterwards the prevention of those calamities afflicting mankind which have received the title of diseases. In other words, he strives to trace diseases from their actual representation, as they exist before us, in their natural progress after their birth, back to their origin, then to seek the conditions out of which they spring; and, further, in investigating the conditions, to see how far they are removable, and how far they are avoidable. The curative side of medical learning thus forms part of his scheme.

The book is an octavo of 740 pages, and though

addressed to the general reader must prove a very useful one to the general practitioner. Parts of the subject, as those concerning poisons and injurious trades, have undoubtedly been much more fully dealt with elsewhere, but the book, as a whole, is a good one, and the point of view deserves still higher commendation as indicative of an excellent tendency in modern medicine.

The Diseases of Children. A Handbook for Practitioners and Students. By ARMAND SEMPLE, B. A., M. B. Cantab., M. R. C. P. London, Physician Northeastern Hospital for Children, Physician to the Royal Society of Musicians, Author of The Voice Musically and Medically Considered, Aids to Medicine, etc. New York: G. P. Putnam's Sons, 27 and 29 West Twenty-Third Street. London, 25 Henrietta Street, Covent Garden. 1884.

In the preface to his work the author seems, strangely enough, to be under the impression that he has done something original in stating that a difference exists between the diseases of childhood and those of adult life. The chapters devoted to diseases of the skin are especially unsatisfactory, though they perhaps represent pretty well the general character of the book, which is that of a compendium, possibly useful to a student preparing for an examination, but markedly deficient in important details of treatment and useful clinical facts.

A Companion to the United States Pharmacopœia. Being a Commentary on the Latest Edition of the Pharmacopœia, and Containing the Descriptions, Properties, Uses, and Doses of all Official and numerous Unofficial Drugs and Preparations in Current Use in the United States, together with Practical Hints, Working Formulas, etc. Designed as a Ready Reference Book for Pharmacists, Physicians, and Students. With over 650 Original Illustrations. By OSCAR OLDBERG, Phar. D., and OTTO A. WALL, M. D., Ph. G. New York: William Wood & Co. 1884. viii. 1216 pages.

This work, the design of which is plainly set forth on its title-page, is the latest and one of the best commentaries that the appearance of the Sixth Revision of the Pharmacopœia of the United States has yet called forth, and is issued by the publishers of that work. The illustrations are nearly all from original drawings from actual specimens. It states plainly, where any exist, the difference in strength and other respects between the last and the previous edition of the Pharmacopœia, and gives concisely the medical properties and uses of all the medicines of which it treats, with the dose. It contains practical information relative to the preparation and use of hypodermic and other injections, as well as inhalations, baths, and other forms of medication, with much other information not usually referred to in books of similar description. It contains very valuable chapters or articles upon the use of the microscope in pharmacognosy, the microscopic structure of plants, the administration of medicines, extemporaneous prescriptions, weights and measures, and specific gravity and volume. By specific volume is understood the relative volume of any weight of a substance as compared with the volume of the same weight of water. The tables given furnish convenient means of converting quantities by weight into volumes by a simple multiplication. Thus as the specific volume of glycerine, U. S. P., is 0.800, 1000 grammes of that fluid measures 800 cubic centimetres, or 1000 avoirdupois ounces will measure 800 imperial fluid ounces.

The work is one which all physicians and pharmacists would find it greatly to their advantage to have for ready reference. B. F. D.

Second Biennial Report of the State Board of Health of Iowa, for the year ending June 30, 1883.

The State Board of Health of Iowa, now in the fourth year of its existence, shows a commendable activity in its last report. Among the more important topics treated are Contagious Diseases, reports of which are tabulated from the returns of clerks and health boards throughout the State.

The distinction between reports of prevalent diseases and mortality reports are not clearly stated in the reports of some of the more recently organized health boards of States. It is encouraging to note progress in this direction in the Reports of the Iowa Board. Reports of prevalent diseases are usually voluntary, and when well done evince a desire to promote the public welfare. On the other hand, mortality reports are commonly made in response to legal enactments, as in Massachusetts, Michigan, Iowa, Rhode Island, and many other States.

Dr. Justin M. Hull, a member of the Board, contributes a paper on Ventilation, in which are briefly summed up the opinions of the best writers upon the subject.

Another paper on Hospitals for Contagious Diseases has a special value, since it reproduces in a concise form the conclusions of a recent English commission relative to the location of small-pox hospitals. It was found on inquiry that after the establishment of such hospitals in thickly-settled districts the disease occurred in their immediate neighborhood, its frequency bearing a tolerably close relation to the number of cases admitted to the hospitals, and hence the necessity for establishing them at places remote from habitations and lines of travel.

Sepulture: Its History, Methods, and Sanitary Requisites. By STEPHEN WICKES, M. D. Philadelphia: P. Blakiston, Son & Co. 1884.

The title of this book is a fair description of its contents. In writing the history of sepulture the author has taken some pains to consult such authorities as are accessible in this country. He confines himself to the duties of a historian, and does not indulge in the advocacy of a system. Much of the book is devoted to portraying the consequences of unsanitary sepulture. The question how and where the dead shall be disposed of is tersely answered in the statement that they should be so buried that the living may not suffer.

The disposal of the dead by cremation or by chemical destruction is not considered. Dr. Wickes very sensibly says in regard to this: "Each method, like the slower processes of decomposition in the earth, resolves the body into its original elements. If good hygiene made it necessary these methods would doubtless be accepted as reasonable and proper. In our

own country the question of their adoption upon sanitary grounds is not an urgent one. It may become so in the generations to come. Inhumation commends itself to the traditional sentiments of the people, and an innovation upon these is not demanded. Rural cemeteries, properly regulated, under wise control, guarded by good laws, and permanently extramural, afford all necessary protection to the public health."

Medical and Surgical Journal.

THURSDAY, MAY 29, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

TREATMENT OF ULCER OF THE STOMACH.

AT the Société Médicale des Hôpitaux, session of April 25th, there was an interesting discussion on the treatment of ulcer of the stomach, in which Drs. Debore, Duguet, Bucquoi, and Gerin Roze took part.

The discussion was opened by Debore, who remarked that the ordinary treatment of simple gastric ulcer by an exclusive regimen of milk and lime water, or milk and Vichy water, often fails. One of the inconveniences attending this treatment is that large quantities are required to sustain the patient, that is, a gallon a day or more, from which irritation and even dilatation may result. The attempt has been made to give an equivalent of milk in smaller volume by using milk powder or condensed milk. These preparations have not been successful in Dr. Debore's practice. The same may be said with regard to the meat powders so much employed in "gleyage" or forced feeding, which are ill borne in gastric ulceration, and often occasion vomiting. In view of this want of success, Debore asked himself if it were not possible to find some other alimentary regimen, which while nourishing the patient would suspend for a time the action of the stomach and suppress the secretion of gastric juice, whose injurious influence on the march of the ulceration is universally conceded. Certain authorities have vaunted the benefits of enemata of peptones, substituting for alimentation by the stomach rectal alimentation, but this means does not enable the organism to be sufficiently nourished, especially if it be necessary to prolong for some time feeding by the rectum.

In view of the impossibility of suppressing the secretion of gastric juice Debore has endeavored to modify its acid reaction by neutralizing it. The acidity of the gastric juice is so characteristic and so necessary for stomach digestion that one may truly say that gastric juice when rendered alkaline has lost all its properties. There is equal reason to believe that it is to this acidity that this secretion owes its power of preventing the healing of the simple ulcer. The problem, then, consists in finding how so to neutralize the gastric juice that azotized food may be given to patients in such a way that the digestion shall be accomplished, not in the stomach, but in the small intestines. With this end in view Debore administered to his patients a certain quantity of meat powder associated with a large dose of bicarbonate of soda; twenty grammes, for instance, of meat powder with ten grammes of the bicarbonate at each meal time. Several trials assured him that the theory which he had adopted was correct; on withdrawing, for example, by the flexible tube the contents of the stomach in patients to whom he had previously given the mixture of meat powder and soda he ascertained that there was no trace of peptones. He treated in this manner four patients affected with ulcer of the stomach; in all these the intolerable pains from which they were suffering and the vomiting disappeared.

At the present time Dr. Debore relies on the following procedure: During the first few days he washes out the stomach to free it of acid matters which it may contain. This operation has never in his practice provoked hæmatemesis, and is regarded as safe; he uses a soft flexible tube, whose extremity if it should hit against the seat of the ulcer could do no harm. In the next place he administers to his patients, three times a day, twenty-five grammes powdered meat, suspended in milk and mixed with ten grammes bicarbonate of soda. This mixture is administered at meal time, and by means of the stomach tube, as it is very disagreeable when taken in the ordinary way as food. The patient is given, besides, a quart of milk a day, rendered alkaline by lime water. The facts go to show that these four patients have taken every day for several months thirty grammes (one ounce) of bicarbonate of soda, and this treatment has never given rise to any of those symptoms which characterize what has been called the "alkaline cachexia."

Dr. Jaccoud, moreover, affirms that he has been able to give to certain patients for a very long time twenty grammes a day (more than half an ounce) of bicarbonate of soda without the least harm resulting. Dr. Charcot has also given from thirty to forty grammes a day of this alkali without noting any sign of cachexia. If it is well established that bicarbonate of soda long continued does not produce cachexia, it is no less true that its employment is attended with certain inconveniences; besides its disagreeable taste its action on the stomach is somewhat irritating, and by its decomposition under the influence of the digestive secretions it sets free a considerable quantity of carbonic acid, which occasions painful eructations. Another reason which has prompted Debore to seek a substitute for the bicarbonate in other alkalies is that the former by reason of its great solubility may be too speedily absorbed, and consequently fail sufficiently to neutralize the gastric juice. He has tried successively to replace the bicarbonate of soda by lime water, saccharate of lime, and magnesia. All these substances have equally their advantages and disad-

vantages, and he now uses that combination which has given the best results. At each meal, which consists of twenty-five grammes of meat powder well stirred into milk, he adds a small package containing a mixture, in about equal proportions, of calcined magnesia and bicarbonate of soda. He also orders the patient to drink each day a quart of milk to which one gramme of saccharate of lime has been added.

In the discussion which followed, Dr. Duguet did not share the opinion of Dr. Debore as to the innocuousness of lavage of the stomach in patients affected with chronic ulcer. He cited an instance of frightful hæmatemesis and death following the use of the sound, which "had produced aspiration at the surface of the ulcer," and provoked the hæmorrhage.

Dr. Gerin Roze did not agree with Dr. Debore in the affirmation that dilatation of the stomach is likely to follow a milk diet in ulcer of the stomach. Every day we see cardiac or nephritic patients put upon a milk diet, and we seldom or never witness dilatation of the stomach in such patients.

Dr. Bucquoi had never observed death from the use of the sound and from lavage in gastric ulcer; he had, however, seen the liquid siphoned out of the stomach in this operation present a decidedly bloody appearance, and he was inclined to ascribe the source of the blood, in part at least, to the aspiration produced by the sound. Hence he was disposed to be very cautious in the use of the stomach tube in these cases. As for dilatation of the stomach, he could not bring himself to consider it as the result of treatment by milk diet; all chronic affections of the stomach, whatever treatment may be pursued, are accompanied by dilatation of this organ. It is the lesion of the mucous membrane, and the paralysis consecutive to the long sojourn of alimentary substances, which causes this augmentation of volume of the stomach. He thought it proper to emphasize this fact in connection with ulcer of the stomach, because the milk treatment, which is on the whole the most certain and reliable, has been, as he believes, wrongly blamed for the dilatation which accompanies the lesion.

Dr. Debore, in closing, said that he did not pretend that the milk regimen gives rise, in all cases of ulcer of the stomach, to dilatation; there are, in fact, some patients who take their milk in small quantities at a time, and who can thus ingest several quarts a day without danger; there are others who have only two or three meals a day, and who drink a bowlful or two of milk at a time, thus forcibly dilating their stomachs. He has, moreover, seen a number of cases of dilatation of the stomach in which the dilatation disappeared when the dietary regimen was modified, and this fact he regarded as in striking confirmation of his thesis.

— At a collision on the New York Central and Hudson River Railroad, near Rochester, on the night of May 22d, unusual nerve was displayed by Frederick Parish, a sleeping-car conductor, who, finding his right arm so crushed as to render its loss certain, coolly ligated the limb near the shoulder-joint with a strap, and amputated it just below with his pen-knife.

THE CEMETERIES AND WATER-SUPPLY OF PANAMA.

THE sanitary condition of such a city as Panama, situated as it is upon one of the great natural highways of the world's commerce, should be at all times a matter of more than local concern and importance, but its bearing upon health and disease in other countries become much more intimate with the prosecution of the work upon the interoceanic canal and the employment upon the isthmus of large numbers of laborers. It is well known that Panama itself has a very trying climate and is a very dirty city. The picturesque impression received when approaching by water is rudely dispelled upon entering the streets. It will probably be long before the unwholesome operations of nature and custom are antagonized by public conscience awakened to hygienic laws. There are, however, two conspicuous and correlated sources of the propagation and dissemination of disease at Panama which are as patent and amenable to correction as they are loathsome, — we mean the cemeteries and the water-supply. The present condition and dangers of these have been described before in these columns in plain language, and we reproduce the following paragraph from a letter by Dr. Heffenger, written in March, 1882, from Panama, and published in the JOURNAL of April 20th of that year: —

"One who has not traveled through Spanish America can form no idea of the happy-go-lucky, indifferent, and general slip-shod state of government. Records are seldom kept, and when they are, cannot be relied upon. After vainly seeking mortuary statistics from physicians and public officials, I paid a visit to the various cemeteries, and by overhauling burial books and questioning the keepers, ascertained that the Catholic (native) interments amount to one hundred monthly, and the foreign to ten, giving an annual death-rate of eighty-eight per one thousand. Of these deaths at least one half are due to malarial (yellow?) fevers, one fourth to small-pox, and the remainder to pulmonary and intestinal diseases, syphilis, accidents, etc, etc. I carefully inspected the cemeteries, and cannot pass on without remarking upon the largest one, the immediate property of the bishop. It was built by the Spanish government nearly two hundred years ago upon a boggy piece of land, a mile to the westward of the city. It consists of three hundred and sixty-five niches arranged in three tiers, forming a hollow square. Only the wealthy can indulge in this ultimate luxury, and upon the demise of one of these favored sons of fortune the body is deposited in one of the niches, sealed up by a suitably engraved tablet, to remain so long as cadaveric rent is paid to the church; but let the defunct's relatives fail to satisfy its rapacious demands, and soon the remains in its coffin is tossed into the swamp, just to the rear of the cemetery, where at all times may be seen the unsightly remnant of ancient and recent dead, old Spanish hidalgos, proud doñas, fair señoritas, and new-born babes lying in a promiscuous heap of putrescence ten feet high, their white staring, tongueless skulls mutely protesting against

such barbaric desecration of the dead. My nerves are well tempered, but I confess this sight filled me with uncontrollable disgust and repugnance. Such a constant source of disease germination and dissemination within a mile of the city, of course, must contribute greatly to its unhealthfulness. Will the new health authorities dare interfere with this right of the church? I think not."

The same story is told, though more at length, in a letter to the *Panama Star and Herald*, April 5, 1884, from Dr. Wolfredhelson, late member of the Panama Board of Health. The statements of the letter are editorially indorsed, and show plainly enough that the conditions portrayed are no better, if not worse, than when our correspondent wrote, and verify his prediction that the old church would prove too strong for the young Board of Health. While the Jewish, the Chinese, and the "foreign" cemeteries are in excellent order, and offer nothing for comment or censure, the two native cemeteries — that owned by the bishop and rented in niches to the rich, and that used for general burial of the poor — offer nothing for commendation, and offend all the senses. In regard to the general cemetery it is simply necessary to state that it covers only three fourths of an acre of ground for an increasing population of 20,000 people, and that it is dug over at least once every year, to give an idea of the centre of disease which it must be.

The condition of the church cemetery is even worse than described by our correspondent, for in September, 1882, an earthquake loosened the walls, and cracked many of the *bovedas* or niches, which in the climate of Panama are veritable ovens filled with putrescent humanity — as long as rents are paid. But the poisonous influences of these two cemeteries are not confined to the air; within a few hundred feet of each of them are wells from which water is drawn and sold for drinking purposes through the city, and from which washerwomen draw their supplies for cleansing and infecting the soiled linen of the inhabitants.

The correspondents of the *Star and Herald* may well exclaim: "This whole isthmus wants sanitary reform, at once, to make it a fitting place for human beings to live on, and to prepare it for the great future that lies before it. Let us hope that some plan of combined wisdom and hygiene will bring about such an ending. Humanity and science demand it."

MEDICAL NOTES.

— It is a wonder that a competent, sensible practitioner has any respect for humanity at all. People are constantly revealing their nonsense in medical matters to him, and he has to grin and bear it as best he may. He finds himself supplanted by a man he knows to be a quack, and is assailed with a series of therapeutic experiences by a larger percentage of the elderly females he is thrown in contact with that is calculated to set an unhardened man crazy. The separation of the true from the false among physicians is truly one of the great social problems. — *St. Louis Globe-Democrat.*

— Our readers doubtless remember an article in an English periodical some time since, by Frances Power Cobbe, making the most sweeping charges of immorality and licentiousness against the medical profession. It has generally, and with reason, been considered beneath the notice of the profession at which it was aimed. But the somewhat inflammable Mr. Punch (whose heart, despite his kyphotic malformation, seems to be in the right place) thus vents his feelings: —

> "She shames her sex, who charges with false tongue
> A great profession with all license lewd:
> Doctors disdain — their withers are unwrung —
> The stingless insults of a prurient prude!"

NEW YORK.

— The twenty-fifth annual commencement of the Long Island College Hospital was held at the Brooklyn Academy of Music Wednesday evening, May 21st, and degrees were conferred upon forty-four candidates. The valedictory was delivered by George L. Hutchinson, and the address to the graduates by the Rev. Albert J. Lyman.

— At a hearing of two large companies before the Brooklyn Board of Health on the charge of poisonous adulteration of coffee, held May 17th, Dr. Elias E. Bartley, chemist to the department, made an elaborate report in which he stated that at the works of one of them the following coloring agents were used: French chalk, gum arabic, charcoal from wood, drop black, yellow ochre with a mixture of clay and hydrated oxide of iron, chrome orange, celestial blue, and turmeric; and at the other: Venetian red, yellow ochre, quinia, indigo, indigo extract (a sulphate of indigo, or indigo carmine), and Persian berries with ochre. Of these coloring matters, he said, chrome orange and celestial blue should be prohibited at once. The others, while not so injurious as these, were used to deceive the public, and should be regarded as adulterations. Coffee which had become spoiled or discolored from sea water, or in any way rendered unsalable, was sent to these mills and made to appear like a good article, and green and unripe coffees was there given the brown color of age and rushed into the market. On examination of the coffees themselves lead was found to adhere in considerable quantity to the pans, and the examination of twenty samples of polished coffee from the market showed that the use of Prussian blue, as well as lead, was very common in coloring coffee. After a prolonged discussion of the matter, Health Commissioner Raymond decided to issue an order prohibiting the use in coloring coffee of chrome yellow or orange or any substance containing lead, celestial blue, or Prussian blue.

— The steamship Polaria arrived from Hamburg on the 23d of May with five cases of small-pox on board, and was detained at quarantine. The surgeon stated that on May 19th the first case was discovered, and that though the patient was immediately isolated, three other cases developed the same day. No other case was noted until the day the port of New York was reached, when one additional case developed. All the ship's passengers were immigrants. The five small-pox patients were sent to the Riverside Hospital on Blackwell's Island, and all the other immigrants were

at once vaccinated. The immigrants will be kept on the ship (which was thoroughly fumigated) until all danger of their communicating the disease is over.

— In the amphitheatre of Bellevue Hospital, on May 22d, Dr. William F. Fluhrer, one of the visiting surgeons, described before a number of the profession a successful operation for the removal of a pistol-ball from the brain through a counter-opening in the skull, and exhibited the patient upon whom the operation was performed. The patient shot himself in the forehead with suicidal intent, and hemiplegia with a semi-comatose condition was caused by the injury. Dr. Fluhrer ascertained the direction of the ball by probing, and then extricated it by means of a counter-opening made at the back of the head, after which drainage was secured by passing a rubber tube through the entire wound. The paralysis gradually cleared up, and the patient is now, three months after the shooting, in apparently excellent health. An unpleasant feature of the demonstration was the publicity given to it, as an account of it appeared in all the daily papers.

— The late Matthew Vassar left in his will a considerable sum of money for the erection and endowment of a hospital at Poughkeepsie on condition that his brother, John Guy Vassar, should contribute an equal amount. The latter willingly consented to do so, and having taken an active interest in the matter the arrangements have now been nearly completed for the establishment of the institution. The trustees have purchased an entire block in a desirable location, and the plans and specifications for the buildings, which will be of brick trimmed with terra cotta, have been agreed upon, and proposals invited for the work of construction. The name will probably be the Vassar Brothers' Hospital.

Correspondence.

CONTAGIOUSNESS OF TYPHOID.

ASTORIA, OREGON, *April* 29, 1884.

MR. EDITOR, — It is a matter of astonishment to me that so much difference of opinion should exist in regard to the contagiousness of enteric fever, when so many medical men have seen cases about which the evidence is as strong as any proof can be to establish the fact.

On the 18th of December my son was brought home with typhoid fever, having been sick three weeks, four days only having been spent in bed previous to his return. He drank water from a well which was dug through sandy soil which was within a few feet of the door of a boarding-house kitchen, from which slops had been thrown for many years. Four other cases occurred in the family with whom he boarded, and no case had ever been in the house before. The well had been dug three months. A beef had been killed within forty feet of this well a few weeks before. My son was put into a well-ventilated room, and no precautions were neglected to disinfect the discharges and keep the patient and his room clean. The discharges were buried immediately. The water which was used for cooking and drinking purposes was taken from a tank, and this was continually supplied by rain. There was no possible way for the water to become contaminated by fæcal matter. The rest of the family were kept out of the sick-room as much as possible, though when the young man died, which he did in seventeen days from perforation of the bowel in consequence of his having, contrary to my directions, been allowed to get upon the night chair, his brothers gathered around him, and kissed him. Three weeks after a boy twelve years of age was attacked, and was sick five weeks. Two weeks after this one left his bed a boy aged sixteen and one six were attacked, and remained in bed six weeks. The eldest had diarrhœa three or four days, the younger one was constipated during the whole time. The fever was continued for four weeks, and then became intermittent rather. Rose spots were distinct.

The treatment was a *great abundance of air from the Pacific Ocean through the windows*, the temperature being modified by a fire in the room, milk, *coffee* instead of alcohol, and *warm baths*. Injections of tepid water were used to open the bowels, and when this failed I had to give two compound cathartic pills at night, which were followed by one stool the next day. These were given *late in the disease*, however, *after all tenderness had gone*.

It is an opprobrium upon our profession that such vast difference should exist in the opinions of medical men in regard to the treatment of this disease, and as to how it is propagated.

Very truly yours, T. T. CABANISS, M. D.,
Late Acting Assistant Surgeon, U. S. A.

RETAINED PLACENTA OF ABORTION.

NEWTON, *May* 10, 1884.

MR. EDITOR, — The discussion in your columns of this week upon retained placenta of abortion leads me to say — what I have often said to medical friends — that I have followed a uniform scheme of treatment with such cases for the last thirteen years; a scheme not of direct interference, but, as I may say, of expectant and protective treatment. I cannot remember that I have had a case that did not turn out well in the end. I have had cases that kept me anxious for days together, — and of what other line of practice must not this be said? — but they turned out right.

Given an abortion at about three months in a reasonably intelligent and obedient patient; the fœtus has been discharged, the secundines retained, and the womb is closed against all but forcible dilatation. The condition to be controlled is hæmorrhage, and this can be controlled. I have reason to know that septicæmia, under these circumstances, is an exceedingly rare condition, and have reason to believe that it is more rare than many physicians think. Thus far I have never seen a case, and I suppose in the thirteen years I have had as much experience in this trying complication — early abortion — as falls to the lot of the average general practitioner.

For the hæmorrhage, present or expected, the patient is instructed to lie quietly in bed, and told how to use suppositories, with which she is provided, the suppository being of *vaginal* size, and made of pure butter of cocoa containing each a scruple of tannin. When the hæmorrhage occurs these, one or two at a time, are passed well up to the os uteri; a firm clot is speedily formed, and thus a soft but effective tampon pro-

vided, which is, in a measure, antiseptic also. This can be broken up and removed at any time, but I have generally found it better to allow it to remain, a new suppository being forced in whenever bleeding returns until, finally, the whole contents of the vagina are expelled with the fœtal envelope attached to its upper portion.

Subordinate points of treatment, for example, the use of ergot, opium, food, stimulant, etc., require careful attention, but do not need to be detailed.

I am disposed to defer to my friend, Dr. Mundé, on matters of gynæcology, but I am also disposed to believe that Dr. Mundé would make less of a task of opening and evacuating a uterus which is high up, is in an early stage of evolution, and is obstinately closed, than I should. Moreover, I think I recognize on the part of the present school of gynæcologists an undue tendency to suggest surgical device, and resort to surgical interference.

Yours faithfully, HENRY M. FIELD.

Miscellany.

THE HISTORY AND PRESENT STATUS OF THE WAVERLEY CONVALESCENT HOME.

IT is always pleasant to notice favorable observations upon our own institutions from the pen of foreigners. We therefore extract from the *Lancet* the following notice by Mr. Burdette, secretary of the General Hospital Fund in London, in regard to the Convalescent Home of the Massachusetts General Hospital at Waverley: —

"The first convalescent institution ever established for hospital purposes in America was opened on April 25, 1882. It is called the Waverley Convalescent Home, and is worked by the trustees of the Massachusetts General Hospital. This home has been erected from a fund of $100,000, which was specially raised for this purpose, $30,000 being spent on the building and furniture, and $70,000 being invested as an endowment fund for the permanent maintenance of the home. The home is intended mainly for the use of the patients at the Massachusetts General Hospital, and both free and paying patients may be admitted. It contains thirty beds for patients, and has two wards of nine beds each, one with three beds, two with two beds, and four single-bedded rooms. The proportion of accommodation for paying to free patients is about one to five, but as the object of the trustees is first to benefit the poor who are unable to pay the expense of procuring fresh air and change, so far none but free patients have been received. This is remarkable, and shows how easily the combined pay and free system works in the general hospitals of America. The whole arrangements at the Waverley Home are admirable, and the cheerful and cleanly appearance of everything fills the visitor with gratification. Every ward, every room, every office, from roof to basement, is admirably arranged and perfectly kept. Indeed, I have never seen a more model institution than the Waverley Convalescent Home. The sanitary arrangements have been very carefully planned, and reflect great credit upon Dr. Whittemore, the able superintendent of the Massachusetts General Hospital. Waverley is about seven miles from Boston. The country around is hilly and well wooded, and the site selected for this convalescent home is a singularly beautiful spot. With all the progressive genius for which the Americans are famed, for some unexplained reason they have not heretofore recognized the advantages of convalescent hospitals. This, the first convalescent home in America, is well worth a visit, and I have little doubt many others will soon be erected."

ABDOMINAL SECTION FOR EXTRA-UTERINE PREGNANCY.

DR. ANGUS MACDONALD opened the discussion before the Edinburgh Obstetrical Society[1] on the recent paper of Dr. Freund on Extra-uterine Pregnancy by a report of two cases of his own, in one of which he operated; the account of this operation is of much interest. The menstruation of the patient ceased in October, 1882. The other symptoms of pregnancy followed. In April, 1883, while working hard she overstrained herself, and had pains like those of labor, followed by swelling of the abdomen and a deep-seated pain in its lowest part. A sanguineous discharge from the vagina ensued with swelling of left leg from the ankle to the hip.

Physical examination in May showed the abdomen generally distended. Resonant all over, except just above the symphysis pubis and toward the right flank, where it is relatively dull. Left flank was quite clear. Measurement round umbilicus thirty-three and three fourths inches.

The vagina was short; the uterus was depressed, the vaginal portion being soft and enlarged like that of a pregnant uterus. There was a tender fullness in the pouch of Douglas. In the right and left fornices, on deep pressure, a rounded mass could be felt. Sound entered five inches, and communicated a feeling of increased resistance as it passed over the endometrium.

A large semi-elastic mass projected into the pouch of Douglas flattening the rectal wall and giving rise to great pain when touched.

During the summer the patient occasionally passed blood and pus per rectum, and though the tumor remained without essential change she was tolerably comfortable, except for some abdominal pain when she attempted to move. In September it was deemed advisable to interfere actively in spite of the fact that there had been evidence of communication between the fœtal sac and the bowel. This communication appeared then to have closed.

The operation was performed October 9th, and after the incision was made it was found that the remains of the fœtus were attached to the right and posterior aspects of the abdominal wall. What appeared to be an abdominal adhesion of the cyst was torn asunder, and the bones of the skull, laid bare by this means, were removed. When this apparent cyst was drawn forward, it was found to consist of about five or six inches of the small intestine, the walls of which, where they lay in relation to the abdominal walls, were thick, softened, and almost gangrenous. In the cavity in which the bones of the fœtus lay there was a considerable amount of fæcal matter. A loop of intestine which was adherent to the part above mentioned was carefully separated from the rest, and was found to contain a fæcal fistula. The

[1] Edinburgh Medical Journal, February, 1884.

whole of the rest of the contents of the cavity in which the fœtus lay were now removed carefully, and the cavity sponged out. The portion of the intestine already mentioned, whose wall formed part of the cyst, was now cut out, and the healthy ends of the bowel brought together as completely as possible by a continuous catgut suture, care being taken to approximate the raw edges completely without including any of the mucous membrane. The stitches were passed very close to one another, and this part of the operation took up a considerable time. The gap in the mesentery was also brought together by continuous sutures.

During this part of the operation there was some hæmorrhage, which was, however, completely arrested by the pressure of the sutures. The edges of the fæcal fistula above referred to, having been thoroughly refreshed, were carefully brought together by catgut suture.

The abdomen was now sponged dry and the wound closed, a large India-rubber drainage tube being introduced at the lower angle of the wound, so as to extend to the bottom of the cyst, and secured in position by passing one of the deep sutures through its texture.

The subsequent progress of the case was favorable in the main, in spite of a fæcal discharge for a few days from the situation of the drainage tube. She left the hospital in good health January 9, 1884.

SCARLATINA CO-EXISTENT WITH TYPHOID FEVER.

THE following case of scarlatina combined with typhoid fever is reported by Dr. Pinnock, of Victoria, in the *Australasian Medical Gazette* for October, 1883: "During the typhoid fever epidemic which occurred in this city last autumn two out of four children in one family were attacked insuccession, an interval of a fortnight elapsing between the onset of the fever in the two cases. The one first attacked, when convalescent, was sent away to the sea-side. When the other (aged six) was still in bed on the 29th May, that being the seventeenth day of the fever, the temperature being 100.1° F., my attention was drawn to his brother (aged four), who, on account of the limited accommodation of the dwelling, slept in the same room. He was suffering from sore throat, high temperature, well-marked scarlatina rash, etc., and subsequently endured a severe attack of the complaint. I did not separate the two, partly because from my experience of the rapid infection of scarlatina I considered it too late to do so, and partly because the only other available room was occupied by the eldest child, a girl aged nine. She, however, also manifested well-marked scarlatina anginosa on the following day (30th May), and on the same day the typhoid-fever patient had sore throat and glandular enlargement, and the next day (31st) he had the scarlatina rash, well out, and typical tongue. His temperature rose a degree when the sore throat attacked him. Next day it was 100.7° F. On the third day (2d June) the rash began to fade, the temperature being 100.1° F. On the third of June the temperature was normal (this according to my calculation, would be the twenty-second day from the onset of the typhoid fever), and continued normal afterwards. The rash disappeared entirely on the 6th of June, and he went through the usual desquamative process. Although convalescence was protracted, he eventually made a good recovery."

"I think there is little doubt that this case was one of double poisoning. In a recent discussion at the Clinical Society of London, Dr. Broadbent held that scarlet fever and typhoid were frequently concurrent. Other speakers, including Dr. Whipham, Sir William Jenner, Dr. Mahomed, Dr. Carafy, and Dr. Andrew Clark, narrated various red rashes occurring in enteric fever which had been mistaken for scarlatina. But from the symptoms and general surroundings of the case above reported I am compelled to regard it as one of co-existent typhoid fever and scarlatina. Scarlatina has already been shown to have occurred concurrently with typhus, proving the possibility of dual poisoning in that disease; why not, therefore, with typhoid also?"

FOOT-BALL ACCIDENTS.

CASUALTIES have again been frequent among foot-ball players during the past week or so. In one case it is to be feared that a fatal termination will result, it being stated that the spine was fractured. Those who approve of the game as played in the present rough-and-tumble manner must rejoice in the termination of a recent match at Oldham. From the commencement of the game much ill-feeling was apparent. In consequence of a decision of the referee one of the sides left the field, amidst the greatest uproar, and free fights were indulged in "all over the ground." The retiring side were not permitted to make their way to the dressing-room, stones and mud being freely thrown at them, while they "were in other ways assaulted." This is not the first account that has reached us of a foot-ball match degenerating into a riotous and disorderly bear-fight, the tempers of the players having evidently been aroused by the uncontrollable brutalities and roughness of the pastime. Advocates of the present system of playing the game speak highly of the manly qualities it calls forth. We reiterate that we fail to see any manly quality evoked by it. It is manifestly a game in which the stronger and heavier side has an advantage over weaker antagonists. It is, moreover, one in which injuries are frequently received which render the player incapacitated for life, and, as a consequence, too often a burden and a dependent upon his relatives for support. The selfish indulgence in an amusement which may bring such misery into a household is not, to our minds, the highest ideal of manly prowess. Certainly no man should unnecessarily expose himself to dangerous accidents unless he has adequate means of support in the event of his becoming crippled for life. Lastly, a game can hardly be considered manly which leads to constant disputes and appeals to the referee, whose decisions are not unfrequently challenged, and, as at Oldham, ends in a free fight and the disgraceful treatment at the hands of the spectators of the side visiting the town. There are many ways in which foot-ball might be much improved. It could be made more simple, and thus many disputes which now give rise to much bitterness would be avoided. By stopping the handling of the ball and running with it (in the "Rugby" game) the dangerous form of accidents would be rendered less frequent; and if it could be so devised that the kicks fell more on the ball and less on the shins of the players the game would become more skillful and less brutal and dangerous. — *Lancet*, March 22, 1884.

REPORTED MORTALITY FOR THE WEEK ENDING MAY 17, 1884.

Deaths reported 2530 (no reports from Buffalo, District of Columbia, and Providence): under five years of age, 892; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 440, consumption 381, lung diseases 295, diphtheria and croup 106, scarlet fever 73, diarrhœal diseases 60, measles 57, typhoid fever 36, malarial fevers 29, whooping-cough 25, small-pox 16, cerebro-spinal meningitis 15, erysipelas 14, puerperal fever eight, typhus fever one. From *measles*, New York, Chicago, and New Orleans 13 each, Baltimore nine, Pittsburg seven, Brooklyn and Somerville one each. From *typhoid fever*, Philadelphia 15, Chicago four, Baltimore three, New York, Cincinnati, New Orleans, and Milwaukee two each, Boston, New Haven, Nashville, Lowell, Gloucester, and Waltham one each. From *malarial fevers*, New York nine, Chicago, Baltimore, St. Louis, and New Orleans four each, Brooklyn three, Cincinnati and Charleston one each. From *whooping-cough*, New York 10, Baltimore four, Brooklyn three, Philadelphia, Boston, and Pittsburg two each, St. Louis and Worcester one each. From *small-pox*, New Orleans 11, Philadelphia four, Cincinnati one. From *cerebro-spinal meningitis*, Chicago and Chicopee three each, St. Louis and Cincinnati two each, Baltimore, Milwaukee, Worcester, and Fall River one each. From *erysipelas*, New York six, Baltimore three, Brooklyn two, Philadelphia, Chicago, and Boston one each. From *puerperal fever*, New York, Brooklyn, Boston, Baltimore, New Orleans, Milwaukee, New Bedford, and Chelsea one each. From *typhus fever*, New York one.

Three cases of small-pox were reported in Cincinnati, St. Louis two; scarlet fever 10, diphtheria two in Milwaukee; scarlet fever 44, diphtheria 25, typhoid fever six, and measles three in Boston.

In 103 cities and towns of Massachusetts, with an estimated population of 1,409,314 (estimated population of the State 1,955,104), the total death-rate for the week was 16.35 against 15.88 and 13.67 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending May 3d, the death-rate was 22.7. Deaths reported 3804: acute diseases of the respiratory organs (London) 360, whooping-cough 173, measles 172, scarlet fever 94, fever 36, diarrhœa 33, diphtheria 17, small-pox (London 10, Liverpool four, Hull and Sunderland two each, Birmingham, Sheffield, and Newcastle one each) 21. The death-rates ranged from 15 in Hull to 29.3 in Wolverhampton; Leicester 16.5; Newcastle-on-Tyne 19.3; Bradford 19.9; London 22; Birmingham 22.2; Sheffield 23.1; Sunderland 24 6; Manchester 24.7; Liverpool 25.2; Blackburn 25.5; Nottingham 25.7; Leeds 28.5. In Edinburgh 20.7; Glasgow 27.4; Dublin 31.5.

For the week ending April 26th, in 170 German cities and towns, with an estimated population of 8,907,985, the death-rate was 25.9. Deaths reported 4438; under five years of age, 1972; consumption 687, lung diseases 568, diphtheria and croup 211, diarrhœal diseases 162, scarlet fever 63, measles and rötheln 52, whooping-cough 47, typhoid fever 42, puerperal fever 24, small-pox (Leipzig and Metz one each) two. The death-rates ranged from 16.3 in Potsdam to 39.3 in Essen; Königsberg 34.4; Breslau 32.8; Munich 36.8; Dresden 23.1; Berlin 25.8; Leipzig 25.6; Hamburg 25.5; Cologne 27.3; Frankfort a. M. 16.8; Strasburg 33.8.

For the week ending May 3d, in the Swiss towns, there were 40 deaths from consumption, lung diseases 40, typhoid fever 31, diphtheria and croup 11, diarrhœal diseases nine, scarlet fever five, erysipelas four, whooping-cough three, puerperal fever one. The death-rates were, at Geneva 22.4; Zurich 31.5; Basle 23.2; Berne 28.9.

The meteorological record for the week ending May 17th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps: —

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM MAY 17, 1884, TO MAY 23, 1884.

WILSON, GEORGE F., first lieutenant and assistant surgeon. Ordered to proceed to Fort Canby, Washington Territory, for temporary duty at that post, relieving Assistant Surgeon W. O. Owen, Jr., U. S. A., who will report in person at these headquarters for further orders. Paragraph 5, S. O. 62, Headquarters Department of Columbia, May 12, 1884.

STERNBERG, GEORGE M., major and surgeon. Relieved from duty in Department of the East, and ordered to report to the Surgeon-General of the Army for temporary duty. Paragraph 2, S. O. 115, A. G. O., May 17, 1884.

MAGRUDER, DAVID L., lieutenant colonel and surgeon. Ordered to be relieved from duty as medical director, Department of the Missouri, and to proceed to Philadelphia, Penn., and assume duties of attending surgeon and examiner of recruits in that city.

FRYER, BLENCOWE E., major and surgeon. From Department of Missouri to Department of Dakota.

EWEN, CLARENCE, captain and assistant surgeon. From Department of Missouri to Department of Platte.

STRONG, NORTON, first lieutenant and assistant surgeon. From Department of Platte to Department of Missouri. Paragraph 7, S. O. 115, A. G. O., May 17, 1884.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING MAY 24, 1884.

MARTIN, W., assistant surgeon, ordered to U. S. S. Constellation.

NELSON, H. C., medical inspector, granted leave of absence for one year.

BALDWIN, L. B., passed assistant surgeon, detached from U. S. S. Pensacola, and waiting orders.

WELLS, H. M., surgeon, ordered to Naval Hospital, Brooklyn.

J. M. MURRAY, passed assistant surgeon, detached from U. S. S. Minnesota, and ordered to U. S. S. Passaic.

WAGGENER, J. R., passed assistant surgeon, ordered to U. S. S. Hartford.

OBITUARY.

PROF. J. B. DUMAS, member of the Académie de Médicine of France, has recently died at an advanced age. He was the author of numerous scientific works, and was an eminent authority in matters of chemistry. In the character of his life-work, the seat of his professorship, and the time of his decease he was closely associated with another distinguished chemist, CHARLES ADOLPHE WURTZ, who died in Paris May 12th. Wurtz was born in Strassburg, November 26, 1817, became chief of the chemical department in the medical faculty at Strassburg in 1839, and took his degree there in 1843. Subsequently he was connected with institutions in Paris and Versailles. After the death of Orfila in 1853, and the retirement of Dumas in 1854, their chairs were united in that of medical chemistry, and given to Wurtz. In 1856 he became a member of the Medical Academy, in 1866 Dean of the Faculty of Medicine, and in 1867 of the Academy of Sciences, at whose suggestion the biennial prize of 20,000 francs had been awarded to him in 1865. On December 3, 1875, he submitted to the French Academy the first specimen of gallium, a new metal discovered by Lecoq De Boisbaudran. He was the author of many valuable volumes on chemistry.

HYSTERIA, AS AFFECTED BY REMOVAL OF THE OVARIES.[1]

BY G. L. WALTON, M. D.

IT is not the object of this paper to discuss oöphorectomy, as such, either from the surgical or the moral point of view, but to consider the question of hysteria as benefited or not benefited by the operation. This operation having, in the face of persistent opposition, forced itself into recognition on purely gynæcological grounds, the neurological aspect of the subject seems now to attract considerable attention, and its importance is not inconsiderable.

That all sorts of reflex nervous symptoms accompany diseases of the uterine appendages is a well-recognized fact. Similar symptoms appear, to be sure, in women with normal reproductive organs, and even in men, facts which have led to the depreciation of the uterine origin of hysteria to that degree that we sometimes meet with the statement that hysteria is *always* a constitutional disease, having no relation whatever to the pelvic organs. Now, although this is undoubtedly the usual character of the disease, there are certainly many cases in which hysteria occurs in persons possessing no constitutional tendency to nervous trouble, the symptoms dating accurately from disease of the pelvic organs. In view of these cases we must take a step backwards towards the ancient view that all hysteria arose from uterine disorder, substituting, however, probably here the ovaries for the uterus as the seat of original irritation. It becomes of practical importance to consider this subject carefully, for if hysteria exists in a given case of pelvic disease in which operation is proposed, and if the hysteria is considered to be dependent on the ovarian irritation, there will be an additional indication for removing the offending organ. Indeed, if the hysterical symptoms reach a certain degree in such a case they may alone furnish sufficient cause for the operation. One finds not infrequently among reported cases of Battey's operation the statement that the reflex nervous symptoms were relieved. Detailed accounts of such symptoms are, however, not common, and it seems probable that among these cases typical and measurable symptoms of hysteria, such as hemianæsthesia, would be oftener found if oftener sought. As a rule, however, the nervous symptoms have occupied the background, the important indication for operation being generally the dysmenorrhœa.

The question of removal of the ovaries for hysteria alone has now been broached, and has already been practically tested with results diametrically opposed.

As an example of unsuccessful operation may be cited the case of Landau and Remak,[2] in which both ovaries were removed on account of hystero-epilepsy, combined with hysterical hemianæsthesia. The ovaries were found normal, and the nervous symptoms were not alleviated in the least. These writers express, therefore, the opinion that the operation for hysteria is unjustifiable, and that the tenderness existing over the ovaries in this disease is merely a hyperæsthesia symptomatic of the general nervous irritability rather than pointing to the source of the nervous trouble. On the other hand, a large number of cases have been reported in which hystero-epilepsy and similar symptoms have disappeared after removal of the ovaries. In the collection of 218 cases made by Battey of the operations between 1872 and 1881 epileptic attacks were present in twenty-six cases, and were relieved in over two thirds of the number. A number of cases have been reported since this collection was made in which hystero-epilepsy has been the chief indication for removal of the ovaries, and has disappeared or been greatly mitigated by the operation.

As examples of such cases may be mentioned two of Carstens',[3] whose histories were briefly as follows: —

CASE I. The patient, twenty-four years old, single, had been a sufferer about five years from dysmenorrhœa, leucorrhœa, and severe hystero-epilepsy, coming on at the menstrual periods. There was no hereditary nervous tendency. Examination showed retroversion of uterus, slight endometritis, internal stenosis of uterus, and ovarian tenderness The left ovary (adherent) was removed, together with a small cyst from the left Fallopian tube. The operation was followed by disappearance of the menses, and by permanent relief of the hystero-epilepsy and the leucorrhœa, at least neither had recurred a year after operation.

CASE II. The patient, twenty-four years old, married, has no nervous family history. Severe ovaralgia came on four years ago, accompanied by pain in the vertex and attacks of hystero-epilepsy, occurring sometimes daily. Examination showed retroflexion of the uterus and exquisitely tender left ovary. This was removed, and found diseased. Perfect cure followed, without remission up to the time of second report, made four months after operation. The conclusions drawn by Carstens are as follows: "In general I might conclude that Battey's operation is not only justifiable, but really we might say it is criminal neglect not to perform it in cases which fail to be benefited by other treatment. It is a last resort after every other proper treatment has failed in cases which are caused by ovarian disease, such as hystero-epilepsy, dysmenorrhœa, and menorrhagia due to fibroid tumors, and which either endanger the life of the patient or make life a burden to her."

These views are certainly justified by experience, and the difference between these results and those of E. G. Landau and Remak seems to lie in the selection of cases. That operated on by the latter writers was one of the large class of hystero-epileptics in which the nervous condition is independent of the uterine appendages. The fact was established by examination of the ovaries after operation that in this case the ovarian tenderness did not result from disease of those organs, but was only indicative of general sensitiveness of the nervous system. As regards this class of cases, which is to say, probably, as regards the large majority of cases of hysteria, the conclusions of Landau and Remak are undoubtedly correct. Such cases, however, as those operated on by Carstens, come under quite another category, in that the hysterical symptoms were manifestly secondary to and dependent on ovarian irritation. It is only with regard to the latter class of cases that the question of operation should ever have been considered for a moment,[4] and the first question to be asked is, Into which class does the case in hand fall?

HYSTERIA, AS AFFECTED BY REMOVAL OF THE OVARIES.[1]

BY G. L. WALTON, M. D.

It is not the object of this paper to discuss oöphorectomy, as such, either from the surgical or the moral point of view, but to consider the question of hysteria as benefited or not benefited by the operation. This operation having, in the face of persistent opposition, forced itself into recognition on purely gynæcological grounds, the neurological aspect of the subject seems now to attract considerable attention, and its importance is not inconsiderable.

That all sorts of reflex nervous symptoms accompany diseases of the uterine appendages is a well-recognized fact. Similar symptoms appear, to be sure, in women with normal reproductive organs, and even in men, facts which have led to the depreciation of the uterine origin of hysteria to that degree that we sometimes meet with the statement that hysteria is *always* a constitutional disease, having no relation whatever to the pelvic organs. Now, although this is undoubtedly the usual character of the disease, there are certainly many cases in which hysteria occurs in persons possessing no constitutional tendency to nervous trouble, the symptoms dating accurately from disease of the pelvic organs. In view of these cases we must take a step backwards towards the ancient view that all hysteria arose from uterine disorder, substituting, however, probably here the ovaries for the uterus as the seat of original irritation. It becomes of practical importance to consider this subject carefully, for if hysteria exists in a given case of pelvic disease in which operation is proposed, and if the hysteria is considered to be dependent on the ovarian irritation, there will be an additional indication for removing the offending organ. Indeed, if the hysterical symptoms reach a certain degree in such a case they may alone furnish sufficient cause for the operation. One finds not infrequently among reported cases of Battey's operation the statement that the reflex nervous symptoms were relieved. Detailed accounts of such symptoms are, however, not common, and it seems probable that among these cases typical and measurable symptoms of hysteria, such as hemianæsthesia, would be oftener found if oftener sought. As a rule, however, the nervous symptoms have occupied the background, the important indication for operation being generally the dysmenorrhœa.

The question of removal of the ovaries for hysteria alone has now been broached, and has already been practically tested with results diametrically opposed.

As an example of unsuccessful operation may be cited the case of Landau and Remak,[2] in which both ovaries were removed on account of hystero-epilepsy, combined with hysterical hemianæsthesia. The ovaries were found normal, and the nervous symptoms were not alleviated in the least. These writers express, therefore, the opinion that the operation for hysteria is unjustifiable, and that the tenderness existing over the ovaries in this disease is merely a hyperæsthesia symptomatic of the general nervous irritability rather than pointing to the source of the nervous trouble. On the other hand, a large number of cases have been reported in which hystero-epilepsy and similar symptoms have disappeared after removal of the ovaries. In the collection of 218 cases made by Battey of the operations between 1872 and 1881 epileptic attacks were present in twenty-six cases, and were relieved in over two thirds of the number. A number of cases have been reported since this collection was made in which hystero-epilepsy has been the chief indication for removal of the ovaries, and has disappeared or been greatly mitigated by the operation.

As examples of such cases may be mentioned two of Carstens',[3] whose histories were briefly as follows: —

Case I. The patient, twenty-four years old, had been a sufferer about five years from dysmenorrhœa, leucorrhœa, and severe hystero-epilepsy, coming on at the menstrual periods. There was no hereditary nervous tendency. Examination showed retroversion, displacement of uterus, slight endometritis, internal stenosis, motor uterus, and ovarian tenderness. The left ovary (adherent) was removed, together with a small cyst from the left Fallopian tube. The operation was followed by the disappearance of the menses, and by permanent relief from the hystero-epilepsy and the leucorrhœa, at least neither had recurred a year after operation.

Case II. The patient, twenty-four years old, married, has no nervous family history. Severe ovaralgia came on four years ago, accompanied by pain in the vertex and attacks of hystero-epilepsy, occurring sometimes daily. Examination showed retroflexion of the uterus and exquisitely tender left ovary. This was removed, and found diseased. Perfect cure followed, without remission up to the time of second report, made four months after operation. The conclusions drawn by Carstens are as follows: "In general I might conclude that Battey's operation is not only justifiable, but really we might say it is criminal neglect not to perform it in cases which fail to be benefited by other treatment. It is a last resort after every other proper treatment has failed in cases which are caused by ovarian disease, such as hystero-epilepsy, dysmenorrhœa, and menorrhagia due to fibroid tumors, and which either endanger the life of the patient or make life a burden to her."

These views are certainly justified by experience, and the difference between these results and those of E. G. Landau and Remak seems to lie in the selection of cases. That operated on by the latter writers was one of the large class of hystero-epileptics in which the nervous condition is independent of the uterine appendages. The fact was established by examination of the ovaries after operation that in this case the ovarian tenderness did not result from disease of those organs, but was only indicative of general sensitiveness of the nervous system. As regards this class of cases, which is to say, probably, as regards the large majority of cases of hysteria, the conclusions of Landau and Remak are undoubtedly correct. Such cases, however, as those operated on by Carstens, come under quite another category, in that the hysterical symptoms were manifestly secondary to and dependent on ovarian irritation. It is only with regard to the latter class of cases that the question of operation should ever have been considered for a moment,[4] and the first question to be asked is, Into which class does the case in hand fall?

[1] Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Suffolk District Medical Society, April 9, 1884.

[3] American Journal of Obstetrics, March, 1883.

[4] Cases of *insanity* accompanying menstruation have indeed been

My second examination was made March 21st, two months after operation. The hemianæsthesia was much lessened, the lightest touch being felt over the entire right side, though not quite so plainly as on the left. The substances which were not perceived at all by smell and taste on the right side before operation were now recognized on that side, though not so easily as on the left. The watch on the temple, previously heard only on the left, was now heard on both sides, best on the left. There was no trace of the wax-like rigidity in the left foot, and that in the right was much diminished, the right foot when bent into an awkward position now falling back directly to a natural one, though not so completely as the left. The reflex spasm of the quadriceps femoris on the right still persisted. The tendon reflex was normal on the left, but still exaggerated on the right, causing a twitch of the whole body, but less marked than before, while the distress caused by the tap was comparatively slight.

The most marked improvement was with regard to the convulsions, previously so severe and frequent, only two light attacks having appeared since the operation. There had been considerable pain in the back and abdomen at the menstrual period, and at this time the patient, at others up and about, was confined to her bed for some days. We cannot, of course, assume that the improvement will be permanent, but the case well illustrates the rôle which hysteria may play as an indication for operation, and the result up to this time has certainly been most satisfactory.

A CASE OF ACTINOMYCOSIS IN A HEIFER.[1]

BY W. F. WHITNEY, M. D.

SINCE attention has been called to this form of parasitic disease a number of cases have been observed in Europe within the last two years. Few, however, have been seen in this country, and, as far as is known, none in this immediate vicinity.

The specimen came from the head of a heifer which had been sent to the Harvard Veterinary School, and was kindly placed at my disposal for examination by Dr. C. P. Lyman, who suspected the nature of the affection.

The disease presented itself as a large fungous-shaped mass, projecting from the lower edge of the right horizontal ramus of the lower jaw near the middle. The surface was granulating and covered with a thick crust of purulent material. The outline was slightly lobulated. Upon section the mass appeared to be composed of lobe-shaped divisions, distinguished by their yellowish color and softer consistency from the intervening tissue. Upon deeper dissection the bone was found invaded throughout its thickness, and a large cavity crossed by bony trabeculæ filled with a pultaceous mass of a dirty yellow color was disclosed. The yellow color, both in the solid portions of the growth and in the semi-fluid substance from the cavity, was found to be confined to numerous irregular-shaped particles about the size of a pin's head. These could be easily isolated on the point of a knife.

Microscopic examination of these particles when fresh showed that they were composed of large numbers of small bodies of an elongated pear shape, sometimes branching, with slightly clubbed extremities. These were arranged side by side radiating from a central point or line, and presented a very characteristic and peculiar appearance. Lime salts were often associated with them, which had first to be dissolved in dilute mineral acid before the nature of the growth could be determined.

Portions of the tumor were hardened in a mixture of two parts Muller's fluid and one part alcohol, and thin sections made from this showed that each of these clumps of radiating bodies was surrounded by a narrow zone of small cells, the size of leucocytes, in a greater or less degree of fatty degeneration. (This must contribute largely to the yellow color of the particles as seen with the unaided eye.) This zone gradually passed into a tissue composed of large contiguous round cells, and which would be designated as sarcomatous.

These appearances correspond to those first described by Israel in cattle, and later by Ponfick in man, and distinguish the disease as produced by the presence of actinomyces or radiating fungi.

The clinical history of the case, as furnished by the owner, is as follows: —

"The heifer was a pure Holstein, born in Massachusetts November 25, 1881. In the spring of 1883 was hooked in the jaw, which swelled badly at first but receded later. In October, 1883, the swelling broke and discharged up to the time of death; at the same time the tumor began to increase rapidly in size. She aborted January 6, 1884, at about the eighth month, and was killed April 8, 1884. The owner had never seen a similar case, nor was there any other among his herd."

The occurrence of this case renders it probable that others, as yet undetected, may be in the neighborhood and may serve as a focus of contagion to other animals and man.

[1] Specimen shown at the meeting of the Clinical Section of the Suffolk District Medical Society, April 9, 1884.

Reports of Societies.

THE ANNUAL MEETING OF THE PENNSYLVANIA STATE MEDICAL SOCIETY, MAY 14, 15, AND 16, 1884.

THE thirty-fifth annual session of the State Medical Society of Pennsylvania was held at Philadelphia from May 14th to 16th inclusive. It was the largest meeting ever held by this Association; nearly four hundred names were registered. DR. HENRY H. SMITH, of Philadelphia, President of the Society, performed the duties of presiding officer with dignity and discretion.

FIRST DAY'S PROCEEDINGS.

DR. JOHN B. ROBERTS, chairman of the Committee of Arrangements, delivered a brief Address of Welcome.

TRIBUTE TO PROFESSOR GROSS BY GOVERNOR PATTISON.

Dr. Roberts was followed by the Governor of Pennsylvania, HON. ROBERT E. PATTISON, in a short address, in which a graceful tribute was paid to the memory of Professor Gross, "that great man whom all regarded with so much pride and veneration; to whose masterly mind two continents paid honor, and

who held the triple tributes of Oxford, Cambridge, and Edinburgh; by whose death the medical profession has sustained a great loss."

PUBLICATION OF PAPERS.

The Committee on Publication submitted a resolution declaring that in future no paper read before this Society shall be printed in the Transactions if it has previously been published in full. An amendment was offered also forbidding the publication of abstracts of papers. In the discussion of this resolution it was declared that some of the members had given their papers or long abstracts of them to reporters of the daily press in order to advertise themselves. The matter was referred finally to a committee of five members to report at the session on Friday.

A WOMAN'S VOICE.

The delegates to the various State Medical Societies made reports, among them being one from the members who visited the Massachusetts State Medical Society, presented by Dr. Alice Bennett, of Norristown. This was said to be the first occasion upon which a woman's voice was heard in the proceedings of this Association. Subsequently the same voice was heard reading the Address upon Mental Disorders in fulfillment of an appointment made at the last meeting. The address was a good one, and was received with applause.

VIVISECTION.

A communication received at the last meeting from the Antivivisection Association, asking that the requirements of experimental medicine and physiology be defined by law in order to avoid unnecessary cruelty was reported upon by a committee to which it had been referred, of which DR. S. WEIR MITCHELL was chairman. In the report all attempts to control vivisection by law were deprecated inasmuch as vivisection had been almost completely stopped in England by the law requiring licenses to be taken prior to performing experiments upon animals. Dr. Mitchell stated that he had applied for snake venom to the government officers in India in order to pursue some investigations upon its nature and effects, and that assistance had been granted to him to conduct experiments in America which could not be conducted in England on account of the law. The passage of the following was recommended: —

Resolved, That in view of the attempts which have been or are to be made to obstruct by restrictive legislation the progress of experimental medicine, this Society desires to express its earnest conviction that experimentation on animals is a most useful source of knowledge in medical sciences; that it is the means by which many important discoveries, both practical and scientific, have been accomplished; that its direction and supervision can be properly intrusted only to members of the medical profession, and that its restriction or prohibition by law would inevitably retard the acquisition of knowledge in respect to healthy and morbid actions, the cause and prevention of disease, and the improvement of the medical art.

On motion the report was accepted, the resolution adopted, and the committee continued.

A STATE BOARD OF HEALTH.

A resolution offered by DR. E. A. WOOD, of Pittsburg, was adopted, calling for the appointment of a committee of seven to prepare and report at the session a plan for organizing a society for securing a State Board of Health.

THE PRACTICE OF PHARMACY.

On motion of DR. J. V. SHOEMAKER the Society indorsed the passage of an act now before the Legislature regulating the practice of pharmacy, and adopting measures to prevent adulteration in drugs and medical preparations as proposed by the Pennsylvania Pharmaceutical Association.

HYGIENE AND STATE MEDICINE.

The address on Hygiene and State Medicine was delivered by DR. BENJAMIN LEE, in which the lecturer dwelt upon the necessity of education of the community in sanitary matters, and the importance of self-help in organizing sanitary organizations in preference to depending upon State boards. Voluntary sanitary associations, such as those first started in Edinburgh, and in Newport, of which there are now one hundred and seventy in active operation throughout this country, were spoken of approvingly for small places, while for large cities stock companies are more suitable. These companies engage to make inspections, both special and periodical, of dwellings and buildings confided to their care, as far as their sanitary condition is concerned; to indicate defects if any exist, and to remedy those defects by introducing sanitary appliances of the best material, most approved pattern, and most scientific construction, under the supervision of thoroughly qualified experts; to furnish plans and specifications for the sanitary system of new buildings and of grounds, and to take complete charge from the outset of the introduction of such systems.

PROPER MEDICAL EDUCATION

was discussed in a paper by HENRY LEFFMAN, M. D. He claimed that the dominant methods of instruction in medical schools are not the results of intelligent effort to meet the needs of the community, but are largely an irregular development. The reforms which medical colleges have adopted have been mostly unwilling concessions to public sentiment. The sevenfold division of branches has nothing to recommend it but antiquity; it is not a convenient nor a scientific division of the subject. Under this arrangement some of the departments of the college course are overcrowded, others have not sufficient matter to occupy the time assigned. Departments like hygiene, mental and nervous diseases, and medical jurisprudence have developed so of late years that they might properly be taught by separate chairs and not made merely subsidiary to other chairs, or limited to spring or fall lectureships. The extension and success of post-graduate schools indicate the direction in which the improvement of the curriculum should be made.

Higher specialization is the necessity of the time. The success which has been attained by dentistry shows that other departments, such as otology, laryngology, etc., might with advantage be pursued independently. There would be no reasonable objection to establishing the degrees of doctor of otology, ophthalmology, and so on, commensurate with the degree of doctor of dental surgery.

A preliminary training for the student before enter-

ing on the study of medicine is so obviously necessary that it need not be argued.

The final work of medical reform will be accomplished when the college is made merely the instructor, license to practice being given by an official board of examiners after a written public examination.

SCHOOL HYGIENE.

DR. T. H. FENTON directed attention to Hygiene in Public Schools, or rather the neglect of it, and pointed out some of the principal defects of construction and administration in our public school buildings.

HEART DISEASE AND INSANITY.

The Address in Mental Disorders was read by DR. ALICE BENNETT, of Montgomery County. Her subject was the Relation of Heart Disease to Insanity, in which she dwelt upon the common occurrence of heart disease in certain forms of chronic mania with delusions and hallucinations, especially of hearing. After giving the histories of sixteen cases, she analyzed the clinical notes of five hundred cases with special regard to the occurrence of cardiac affections.

DR. R. H. CHASE read a paper on the

PROTECTIVE RIGHTS OF THE INSANE IN PENNSYLVANIA.

The Pennsylvania Hospital for the Insane was established in 1751; it was the first of the kind in America. The Friend's Asylum for the Insane at Frankford was started in 1817, and, like the former, is still in active operation. State hospitals for the insane poor were established at Harrisburg in 1845, at Dixmont, 1853, Danville, 1871, Norristown, 1880, Warren, 1880. The establishment of the Commissioners in Lunacy last year in this State was an additional protection to the insane; and he believed that Pennsylvania was now fully abreast with the world in this respect. The removal of all insane persons from almshouses and prisons is now decreed by law; before long it is hoped that separate provision shall be made for the chronic and criminal insane.

METHODS OF INSTRUCTION AT MEDICAL SCHOOLS.

A resolution was offered by DR. JOHN B. ROBERTS expressing dissatisfaction with the methods of instruction pursued at the medical colleges in this State, and forming a committee of seven to consider the propriety of establishing a new school directly under the auspices of the State Society, in which the requirements of the Society with regard to preliminary education, length of course (three years graded course), and final examination by an independent board of examiners, would be complied with, *provided* that if the colleges in Philadelphia adopt these changes no further steps shall be taken in the matter. The subject was laid upon the table.

SECOND DAY'S PROCEEDINGS.

The Treasurer reported a balance of $2451.85 on hand. The report was accepted, after auditing.

THE ADDRESS IN MEDICINE

was delivered by DR. W. H. DALY, of Pittsburg. The speaker referred to the beneficial effect of the germ theory of disease in leading operators to practice scrupulous cleanliness in surgery, but stated that the original observations upon which these theories are based could not be conducted in this country for want of government aid, but clinical study, by which these views are to be tested, is carried on by every physician. The discovery of Jenner was quoted as an illustration of what a country physician could do. The labors of Pasteur and their great value were mentioned, but he did not consider them worthy to be compared with Jenner's services to humanity. With regard to specialties in medicine he deplored the shallowness of some specialists, and repeated Dr. Hodgins' statement that "a specialist, in the best sense, should be a physician and something more; but in the worst sense a specialist is something worse than a physician and something less." Many additions to the science of medicine by the labors of specialists were briefly mentioned, and he concluded by stating that this, after all, is only the natural process of growth. Science has always been advanced by labors in special lines of research.

DR. C. W. DULLES read a paper on

DISORDERS MISTAKEN FOR HYDROPHOBIA,

in which he dwelt upon the rarity of true rabies and the probability of other disorders being mistaken for it. Among those which had been mistaken for hydrophobia he enumerated diseases of the alimentary canal, of the respiratory apparatus, of the circulatory apparatus, various systemic disorders, and nervous diseases. The similarity in the symptoms with those of acute mania, tetanus, and epilepsy was especially pointed out; many cases of reported hydrophobia are simply hysterical.

EXTERNAL TREATMENT IN SKIN DISEASES.

DR. ARTHUR VAN HARLINGEN read a paper on The Principles of External Treatment in Diseases of the Skin, in which he essayed to classify various topical remedies according to their effects upon the diseased skin, as protectives, sedatives, astringents, anæsthetics, stimulants, caustics, and mechanical agents. The object of this classification was to suggest lines of treatment which might aid the general practitioner, who might be discouraged with the nomenclature, but still would wish to treat the patients suffering with skin eruptions.

A NEW SPHYGMOGRAPH.

DR J. H. MUSSER exhibited a modification of Pond's sphygmograph, suggested by Dr. Matur, of Worcester, Ohio, in which the base of the instrument is narrowed so as only to cover the radial artery, instead of being broad and elliptical. The advantages of this modification in affording a more correct indication of the pulse were insisted upon, and admirable tracings were exhibited made by the new instrument.

JEQUIRITY IN SKIN DISEASES.

DR. JOHN V. SHOEMAKER read a communication upon Jequirity and its Use in Diseases of the Skin, in which, after referring to its method of use and action in eye-practice, he spoke of its employment in skin diseases, and exhibited patients who had been affected by lupus, but who had been cured by the infusion of jequirity. It had also been useful in sloughing ulcers and epithelioma, but a much stronger infusion is required than is usually used for ophthalmological practice.

Papers were also read by Drs. J. B. Potsdamer, on Bronchitis and Pneumonia of Rheumatic Origin; Traill Green, A Plea for Chemistry; and Benjamin Lee, on Massage the Latest Handmaid of Medicine.

ELECTION OF OFFICERS.

In the afternoon the Nominating Committee reported the following, who were thereupon elected officers for 1884–85 : —

President, E. P. Allen, of Bradford.

Vice-Presidents, Jacob Price, of West Chester; D. M. Bland, of Columbia; S. Brandeis, of Erie; and S. R. Rutledge, of Indiana.

Permanent Secretary, William B. Atkinson, of Philadelphia.

Recording Secretary, A. J. Connell, of Lackawana.

Corresponding Secretary, John G. Lee, of Philadelphia.

Treasurer, Benjamin Lee, of Philadelphia.

Committee on Publication, John B. Roberts, Henry Leffman, and E. Jackson.

Judicial Council, Traill Green, of Northampton; J. A. Ehler, of Lancaster; H. B. Bishop, of Titusville.

The next meeting will be held on the second Wednesday of May, 1885, at Scranton, Lackawana County.

Chairman of Committee on Arrangements, J. F. Everhart.

On motion Dr. Roberts was allowed to withdraw from the Committee on Publication, and the name of Dr. R. J. Dunglison was substituted.

THE ADDRESS ON OBSTETRICS

was delivered by DR. JACOB PRICE, of West Chester. After a brief review of recent evidences of material progress in obstetrics, he took up several topics of present interest. Pernicious vomiting was ascribed to a local congestion or inflammation of the cervix uteri; in its treatment he recommended salines and topical applications, especially of iodine and carbolic acid. In abortion and flooding the use of the tampon was advocated, with rest and opium. Flexions were considered among the principal causes of miscarriage. In delay during the first stage of labor he preferred morphia and chloral to forced dilatation of the os. Placenta prævia, puerperal convulsions, and puerperal fever were also discussed. With reference to convulsions he said that, over-stimulation being the cause in most cases, chloral, bromide, and chloroform may be used, and in severe cases venesection answers the best of all. In puerperal fever antiseptic vaginal irrigation was considered an important feature in the treatment.

DIPHTHERIA.

L. B. KLINE, of Columbia, read a paper on Diphtheria, based upon his experience in an epidemic. He defined it to be an acute, specific, contagious, and infectious disease of a miasmatic character, probably primarily a local affection. Lactic acid was recommended as a local application to dissolve the membrane, with inhalations of steam and carbolic acid. Internally the iron and quinine treatment was considered indispensable; potassium chlorate and permanganate, sodium sulphocarbolate, bromine, sodium salicylate, eucalyptus, and other agents have also been employed with advantage.

By invitation of the Society, Dr. H. C. WOOD gave the result of his experiments made in conjunction with Dr. Formad to determine the pathological character of diphtheria. He declared that there is a mild and a virulent form of diphtheria, and that the micrococci found in the typical cases of diphtheria do not differ from those found in a healthy mouth; the micrococci must derive their toxic effect from accidental and external circumstances. The disease, as the rule, begins by local infection of the mucous membrane, which becomes crowded with micrococci; these rapidly multiply between the cells of the mucous membrane, necrosis follows, and ulceration is produced. Subsequently, the lymphatics are invaded, and next the blood, even the white blood cells. It was found that diphtheria is not a specific affection, because inoculation with various septic agents led to the production of the false membrane, and the same micrococcus was found in cases of scarlatina, when the invasion of the white corpuscles by the parasite was found to be a valuable prognostic sign. What is commonly called "diphtheria" is, therefore, only a putrid sore throat.

The Work of Woman Physicians in Asia was the subject of a communication DR. MARY H. STINSON, which contained a strong plea for the education of women in medical science for foreign missionary work.

DR. MCFERRAN'S OBSTETRIC FORCEPS.

DR. J. A. MCFERRAN exhibited his obstetric forceps, which are jointed at the junction of the blades and shanks, in order to permit flexion or extension of the head, and avoid some of the dangers of the ordinary forceps. He also made some remarks upon the mechanism of parturition, in order to explain the peculiar advantages of this form of forceps. These instruments were designed in 1877, and presented before the Philadelphia County Medical Society the same year.

DR. BENJAMIN LEE made some remarks upon

THE TREATMENT OF HIP-JOINT DISEASE,

and showed two forms of splints that he was in the habit of using. He also exhibited a case which had come under his care when in the third stage, sinuses having formed around the joint; the case was now presented with the two limbs corresponding in length, and with perfect mobility of the hip-joint. At his suggestion a committee of three was appointed to examine the patient and report.

MEDICAL DIPLOMAS.

On motion of DR. JACKSON a resolution was adopted as follows : —

Resolved, That a committee of seven be appointed by the chair to inquire as to the best method of making the diploma, which permits a man to enter upon the practice of medicine in the State of Pennsylvania, a real guarantee of his proper qualification for the work, the committee to report at the next annual session of this Society.

By another resolution this report was made the order of business for the morning of the second day of the next session.

PRESIDENT'S ADDRESS.

In the evening the Annual Address[1] of the President, DR. HENRY H. SMITH, was delivered at Association Hall, his theme being the Usefulness of Scientific Medical Organizations to our Profession and the Public. In connection with State Medicine the capital punishment of criminals by the usual method was condemned as not being in accord with the scientific progress of the age, and the suggestion was made that the Legislature be memorialized to adopt electricity as the agent to destroy life.

(To be concluded.)

[1] See pages 481 and 507 of the JOURNAL.

THE AMERICAN CLIMATOLOGICAL ASSOCIATION.

THE first annual meeting of the American Climatological Association was held in Washington, D. C., May 3d and 5th.

In the absence of Professor Loomis, the President, DR. F. I. KNIGHT, of Boston, first Vice-President, occupied the chair.

ADOPTION OF CONSTITUTION, AND READING OF PAPERS.

The first day was occupied in adopting a suitable Constitution and By-laws.

The second day was devoted to the reading of papers, as follows: —

Address by the presiding officer, DR. KNIGHT.

The Ætiology of Pulmonary Phthisis, by DR. B. F. WESTBROOK, of Brooklyn. The Effects of Sea Air upon Diseases of the Respiratory Organs, by DR. BOARDMAN REED, of Atlantic City. The Relation of Laryngeal Disease to Pulmonary Diseases, by DR. F. H. BOSWORTH, of New York. On Dryness, by DR. CHARLES DENNISON, of Denver, Col., in which he dwelt on the following points: Variability *versus* Equability; a rule for classifying climates as to dryness and desirability, based upon low, absolute, and relative humidities and preponderance of sunshine; the influence of elevation, sunshine, cold, etc., in producing desirable dryness; the physical effect of dryness on man. City Life and City Air Injurious to Consumptives, by DR. DONALDSON, of Baltimore. The Use of Compressed and Rarefied Air as a Substitute for Change of Climate in the Treatment of Pulmonary Diseases, by DR. J. SOLIS COHEN, of Philadelphia.

ELECTION OF OFFICERS.

The following officers were elected for the ensuing year: —

President, Prof. A. L. Loomis, New York; First Vice-President, Dr. F. I. Knight, Boston; Second Vice-President, Dr. W. H. Geddings, Aiken, S. C.; Secretary and Treasurer, Dr. J. B. Walker, Philadelphia; Council, Dr. J. H. Tyndale, New York; Dr. E. T. Bruen, Philadelphia; Dr. E. D. Hudson, New York; Dr. Frank Donaldson, Baltimore; Dr. Beverly Robinson, New York.

NEW YORK ACADEMY OF MEDICINE.

AT a stated meeting of the Academy held May 15, 1884, DR. D. BRYSON DELAVAN read a paper entitled

PRACTICAL SUGGESTIONS UPON THE ALIMENTATION OF PATIENTS SUFFERING FROM DYSPHAGIA.

In opening he alluded to the extreme suffering experienced in dysphagia, which came like an overwhelming blow upon patients already prostrated with disease of a serious, if not absolutely fatal, character. The conditions giving rise to dysphagia were of an organic or functional nature or, again, might be caused by surgical operations, and the trouble might be either acute or chronic. Among the organic affections were mentioned tuberculosis, cancer, syphilis, diphtheria, tonsillitis, and retro-pharyngeal abscess, and among the functional, spasm of the constrictors of the pharynx. In dysphagia there might be mechanical interference with deglutition besides pain, direct or reflex, and the result was always, of course, impairment of nutrition. When it occurred the first indication was to give the parts concerned in swallowing rest as far as possible, and sometimes the feeding of the patient with raw eggs or the use of local anodynes was all that was required. In some acute affections of the throat the act of deglutition caused intolerable suffering in spite of such measures as these, and it was, therefore, essential to abolish the act of deglutition. In cases where there was gastric impairment from any cause rectal alimentation was invaluable, but if, on the other hand, the stomach was in good condition it was highly desirable that food should be introduced directly into it if possible. If the cause of the dysphagia was not removable the method to which he now desired to call attention, Dr. Delavan said, would be found very efficient for this purpose. The basis of it was founded on the stomach tube, and he then proceeded to give a summary of the history of that device, and the applications which had of late years been made of it. Unlike the old tube hitherto employed the one which he recommended was of much smaller size. The principles of the method to which he wished to direct attention were (1) to use a tube of the smallest possible calibre that would serve the purpose, and (2) not to pass it all the way to the stomach, but only past the point of constriction of the œsophagus, if any such were present. In many cases it was simply necessary to carry it past the pharyngeal constrictors. By the use of this method pain was done away with, rest was insured, injury to the parts was avoided, and nutrition was maintained.

The apparatus was of a very similar nature, and consisted, first, of a receiver, for which an ordinary soda bottle answered better than anything else on account of the conical shape of its bottom, which rendered it easy to withdraw all the fluid at the same time that it diminished the risk of pumping air into the stomach. From the cork, through which a rubber tube passed to the bottom of the receiver, there issued two tubes, one connected with an ordinary Davidson air-compressor, and the other attached to a catheter (inside of which there was usually a small glass tube), which was to be carried into the œsophagus. The essential feature was the catheter, which might range in size from No. 9 to No. 18, English scale, the one exhibited being a No. 9. It was thus very much smaller than the smallest of the three sizes of stomach tube ordinarily in use. It was advisable that an orifice should be made in the point of the catheter so as to allow of the free passage of fluid. The prepared food was to be allowed to run very slowly into the œsophagus, and Dr. Delavan said that he found it convenient to use an ordinary "cut-off" until all the arrangements for the feeding were completed. At first but half an ounce of fluid should be given continuously.

Fourcher had used an even simpler apparatus, a glass funnel connected with the tube, and Dr. Frank Donaldson, of Baltimore, had employed a fountain syringe. Even an ordinary Davidson syringe had been used for the same purpose. Dr. Delavan said he would not stop to speak of the various preparations of food which might be employed in this way, of which the number was unlimited, and for a notice of which he would refer his readers to the articles of Dujardin-Beaumetz and the recent papers of Dr. H. C. Millard in the *New York Medical Journal*.

In describing the method of introducing the catheter

into the œsophagus, he said that the larynx could be avoided by using the finger as a guide. For the purpose of lubricating the instrument (which was never to be neglected) white of egg, mucilage, or milk were excellent, but glycerine and oil were to be avoided on account of their disagreeableness to the patient. A patient of intelligence could soon learn to introduce the tube with more comfort to himself than could be done by the physician. Its passage, however, was not always an easy or painless operation. When the introduction gave rise to dyspnœa Dujardin-Beaumetz directed that the patient should take full breaths, and when it excited nausea that bromide of potassium should be given for a day or two beforehand.

The latter part of the paper was devoted to a consideration of the special applications of the method. He first spoke of its employment in tuberculosis, and said that in no complaint was it more useful. If there was a tubercular deposit in the region of the epiglottis or about the tonsils deglutition caused more suffering than in any other throat trouble. With the chance thus afforded of maintaining a full diet the condition of affairs became greatly changed, and in some cases the possibility of recovery or at least a considerable prolongation of life was afforded. Dr. Delavan then went on to speak of its application in cancer, syphilis, diphtheria, acute tonsillitis, parotiditis, and retro-pharyngeal abscess. In referring to its use in functional disorders he said that dysphagia from spasm of the pharyngeal constrictors was a comparatively rare occurrence, but when it did occur a few well assimilated meals would probably contribute more than anything else to break up the attack. In faucial paralysis from cerebral hæmorrhage, embolism, or diphtheria it was often of service, on account of the well-known tendency of the food to get into the larynx, and hence, in his treatise on diphtheria, Dr. Jacobi had recommended artificial feeding in certain cases of diphtheritic paralysis. When the tube was to be employed after a surgical operation it was advisable to accustom the patient to its use before the performance of the operation. This method being, therefore, of great service in such a variety of conditions, he urged that it should be given a fair, patient, and intelligent trial in all appropriate cases.

The discussion of the paper was participated in by Drs. John C. Peters, E. C. Harwood, Brandeis, George L. Peabody, and W. C. Jarvis, and brought to a close by Dr. Delavan, after which Dr. R. W. Taylor read a paper on

CHANCRE OF THE TONSILS.

Having mentioned that he referred to true chancre as opposed to chancroid, he remarked that this initial lesion of syphilis was not so rare as had been generally supposed. *Origin.* It came either from kissing, from the placing of pencils, bottles, cigars, or other articles in the mouth, or from depraved and unnatural sexual contact, which, he regretted to say, he feared was becoming alarmingly frequent in the community. He then proceeded to mention four cases which he had personally seen. The first was in a boy, nine years of age, under the care of Dr. McBurney at Bellevue Hospital for fracture of the leg, and was contracted from bestial practices. The second occurred in a young woman of loose habits, and was ascertained to have been contracted in the same way. The other two occurred in men, and one of these also was certainly due to the same cause. He then mentioned two others which he had not seen himself, but which had been reported to him by gentlemen of the highest authority. One was told to him in minute detail by the late Prof. Freeman J. Bumstead, and the account of the other was given him by Dr. Edward Wigglesworth, of Boston. It was that of a medical student who contracted chancre of the tonsil by placing his mouth in contact with that of a newly-born asphyxiated infant.

Having referred to seven cases which had been reported by European writers (four of which occurred under the observation of Fournier), he went on to speak in detail of the history and symptoms of chancre of the tonsils. At first there were redness and swelling, but no perceptible glandular complication. As time went on, induration and ulceration of the tonsil were noticed, with a grayish-white coating irregularly spread on it; while the neighboring lymphatic glands began to be enlarged and matted together. He then spoke of the differential diagnosis between mucous patches, syphilitic sclerosis, and epithelial cancer, on the one hand, and chancre of the tonsil on the other; summing up the points of diagnosis of the latter as follows: —

(1.) The details of the manner of infection.

(2.) The slow development of the lesion, running a subacute course.

(3.) Its unilateral position.

(4.) Difficulty of deglutition, and even pain, which is referred to one side.

(5.) The special implication of the pre-auricular gland.

(6.) The comparatively little induration and enlargement of the glands at a distance.

In the discussion which followed the reading of the paper, Dr. F. N. Otis stated that while he had never seen a case of chancre of the tonsil, so far as he remembered, he saw no good reason to doubt why the lesion should not occur as well there as in many other parts of the body. All that was requisite for syphilitic infection was a *contagium* and an open surface for it to lodge upon. He thought, however, that all the diagnostic points referred to by Dr. Taylor would not be found in certain instances, and, therefore, that it was not safe to decide in these cases that because they were not all present the patient did not have an initial lesion of syphilis. Such initial lesions were by no means always characterized by ulceration, for instance, and he had frequently seen a simple little hard nodule on the genitals, after being the means of infecting the system with constitutional syphilis, become absorbed without having undergone any process involving destruction of tissue whatever. In order to show what peculiar forms the initial lesion sometimes assumed, he related a case in which it was distinctly demonstrated that a little red point on the conjunctiva was the source of the whole trouble.

Dr. F. R. Sturgis had also seen four cases of chancre of the tonsil. One was that of the boy in Bellevue Hospital, the history of which had been given in the paper, and of the others one occurred in a man and two in women. In three there was a considerable amount of active inflammation, while in the fourth the symptoms were less acute. The correct diagnosis of the condition, he considered, depended in great part on the enlargement and induration of the pre-auricular and post-auricular glands, and especially of the former. There could be little doubt of the nature of the case when this was distinctly marked.

Dr. L. D. Bulkley remarked that he thought this

was one of the most useful papers that had been read before the Academy for some time. Twenty years ago, he said, no one would ever have thought of looking for the initial lesion of syphilis in the tonsils, and one of the most important points about Dr. Taylor's paper was, that it directed attention to another place in which such a lesion was liable to occur. Not long since syphilis had been regarded as entirely a venereal disease; but since it had been shown in how many ways the infection could be introduced into the system it was no longer considered as necessarily a reproach to be affected with it. He had himself seen four cases of chancre of the tonsil, and one of these he related in detail. It was that of a single lady, thirty-two years of age, of irreproachable character, who contracted it from kissing a man to whom she was engaged to be married, who was suffering from syphilis at the time. It proved to be one of the most severe and terrible cases of constitutional syphilis that Dr. Bulkley had ever met with; and in consequence of the character of the lady the true nature of the trouble was not recognized by the family physician until it had been pointed out by the speaker. Such a paper as this, he thought, therefore, was of the greatest practical importance, as indicating to the general practitioner a possible source of danger from syphilis in a situation where he would probably not otherwise have thought of looking for it.

DR. W. C. JARVIS thought that there was more dread than there need be of chancre occurring in this position, because there was a constant stream of mucus and saliva bathing the throat and pouring down into the stomach; thus preventing syphilitic virus, when introduced into the mouth, from obtaining a foothold. Chancre of the tonsil was a very rare condition, and this, he believed, was the reason why it was so.

DR. TAYLOR said he was quite well aware that there was, as Dr. Otis had pointed out, much variation in the appearances of the initial lesion of syphilis in many parts of the body. But in the tonsil he contended that the appearances did not vary to nearly as great an extent as in some other locations, and that hence the most of the diagnostic points which he had indicated might reasonably be looked for in chancre in that position. But even if the true nature of the affection were not immediately recognized, the patient would not suffer thereby, for as soon as the constitutional symptoms made their appearance there could no longer be any doubt about it; and when this occurred was the correct time to commence with anti-syphilitic treatment. He agreed with Dr. Sturgis that the cardinal point in the differential diagnosis of chancre of the tonsil was in the condition of the glands characteristic of this affection. As to Dr. Jarvis's statement that there was needless dread of it, he was quite willing to admit that chancre of the tonsil was a comparatively rare condition; but, at the same time, as it was one which was liable to be occasionally met with, it would not do to disregard it altogether. As undoubted cases had actually occurred in the past, it was certain that from time to time they would again make their appearance.

— The German government has appropriated 135,000 marks for compensation to the Cholera Commission. Dr. Koch gets 100,000 marks, and the rest is distributed among his colleagues.

NEW YORK COUNTY MEDICAL ASSOCIATION.

ALBUMINURIA.

AT a meeting of the Association held Monday evening, May 19th, DR. GASPAR GRISWOLD read a paper entitled Notes on Albuminuria. Since testing the urine for albumen had become such a common practice among medical men, and especially by those holding the position of examiners in life insurance companies, he said, the presence of albuminuria was no longer regarded as any positive proof of disease of the kidneys, or at all events of disease of a serious character. During the last few years albumen had frequently been noticed in the urine of individuals in apparently perfect health, either as a condition lasting for several years, a transient condition, or an intermittent condition, appearing at certain hours of the day and being absent at other times.

Having expressed the opinion that this condition of albuminuria in those in good health was probably due in reality to some more or less temporary inadequacy of the renal epithelium, which when its integrity was complete permitted only the constituents of normal urine to escape, he alluded to a number of conditions which were liable to be associated with a greater or lesser degree of albuminuria. Among these were hysteria, anæmia (especially at the time of puberty), and the presence in excess in the system of certain substances such as the biliary principles and iodide of potassium. It would seem, therefore, that there was a temporary degeneration of the renal epithelium, which attended the excretion of a large amount of solid constituents by the kidneys.

He then gave an abstract of the literature relating to this subject, and dwelt particularly on the statements of Sir William Gull, Moxon, and George Johnson; concluding with a reference to a paper published by Dr. Munn in the *New York Medical Record* of March 22, 1879, in which he reported twenty-four cases of albuminuria (in two instances accompanied by casts) occurring in persons applying for life insurance in the company for which he was examiner who were apparently in perfect health, but all of whom were rejected on this account. As to the effect of exercise in producing albuminuria, Dr. Griswold stated that he had himself made repeated examinations of the urine of twenty-four individuals after taking violent exercise which was, as a rule, followed by cold shower baths, and in not a single instance was he able to detect the smallest trace of albumen. In this connection he related the case of a gentleman who applied for a policy in the New York Life Insurance Company, but was rejected because his urine, which was examined in the afternoon, just after he had been taking a boxing lesson, was found to contain albumen. The following month he was persuaded to apply for insurance in another company, and on this occasion he was accepted, as no albumen was found in his urine and he was otherwise in excellent condition. Having mentioned that albumen had been found in his urine a month previous, however, several very careful examinations were made, and one of them revealed the fact that the urine was not only highly albuminous but also contained both fatty and granular casts. This examination, like that in the other company, was made in the afternoon, just after the applicant had taken a boxing lesson, and in consequence of the condition of the urine he was again rejected. He then consulted Dr. Janeway in reference to his urine;

but the latter examined twelve specimens of it in succession without finding anything abnormal about it whatever. He then inquired what he had been doing before passing the urine in which the albumen was found by the life insurance examiners, and, learning of the boxing, he secured specimens which were passed for several successive days just after taking this exercise, and found albumen and casts in them all. The importance of one such case as this, he thought, could not be exaggerated.

In speaking of the supposed effect of imperfectly digested albuminous food in producing albumen, he stated that it had been found that if the albumen of eggs were injected into the blood, it would not be assimilated, but might be recovered from the urine, into which it passed. Hence it had been argued by some that if albuminous food were eaten in excess a portion of the albumen would not be digested, and would appear in the urine. With a view of testing the correctness of this view he had experimented very thoroughly on himself, repeatedly taking as many as six eggs at a meal, both raw and cooked in various ways. On no occasion whatever was this ingestion of egg-albumen followed by the appearance of albumen in the urine, and the same was true in the case of a number of friends of his whom he had persuaded to try the same experiment. In one instance, it was true, the examination of the urine showed the distinct presence of albumen; but on investigation it was ascertained that albuminuria existed in this case whether eggs had been eaten or not. Some eighteen individuals engaged in this experiment, and he was therefore inclined to believe that the hypothesis of imperfectly digested albuminous food as a cause of albuminuria was not well founded.

From his investigations of the whole subject of albuminuria, Dr. Griswold arrived at the conclusion that the kidneys were probably liable to be affected with slight and transient disease just as other organs of the body were; and in this connection he related the case of a young physician who for seven years after an attack of scarlatina, which occurred in his youth, was the subject of albuminuria. For the last four or five years, however, his urine had been entirely free from albumen. He also mentioned the case of another physician who five years ago was seized, at the same time with an ordinary cold in the head, with a sharp pain in the lumbar region. He attributed this simply to lumbago, but a medical friend having jokingly suggested that he had better examine his urine to see whether he was not suffering from Bright's disease, he did so, and found to his surprise that it contained not only albumen but hyaline casts also. After five days, however, both the albumen and casts disappeared, and had never since been detected in his urine.

The discussion of the paper was opened by Dr. Austin Flint, Sr., who said that in addition to the subject of albuminuria he should like to have that of the significance of casts also considered; since these, like albumen, were not infrequently present temporarily in the urine of those in apparently perfect health. Such conditions of the urine were apt to lead the attending physician to make a prognosis which was not borne out by the subsequent course of events. He then related the case of a young girl of fourteen in whose case it was accidentally discovered that both albumen and casts were present in the urine. After a time, however, they disappeared altogether, leaving her in excellent health.

Dr. William H. Welch remarked that every one who was accustomed to examining urine at all on a large scale from time to time met cases such as had been described, in which if there was any disease of the kidneys at all it must be of a very trifling character. Medical students were sometimes surprised to find albumen in their own urine, he said, and he then mentioned the case of one to whom this occurred only two days before. The young man was apparently in good health, but had been working unusually hard. To the presence of albumen alone, and sometimes to that of casts in addition, he would attach no significance, and he thought it was often hazardous to make a diagnosis of Bright's disease even when, in addition to these, some impairment of the health was noticeable.

Dr. E. G. Janeway related the case of a broker, in apparently good health, whose urine, passed early in the morning or late at night, when the cares of the day were over, never contained any albumen, but which was actually loaded with it at most other times, a fact which he was disposed to attribute principally to nervous influence. A moderate amount of albumen in the urine when taken by itself was not now regarded as of much consequence, but in this instance the quantity of albumen was so exceedingly large that although the individual was still apparently in excellent health it would be a matter of great interest to watch the future history of the case. The case which had been related in the paper as having been under his care was even more remarkable. After the gentleman had taken his boxing lesson there were always hyaline and sometimes granular casts as well as albumen in the urine, and the case would seem, therefore, to show that it did not take as long for hyaline casts to form as had generally been supposed.

Dr. Flint having called attention to the fact that the occurrence of uræmic poisoning depended not on the presence of albumen in the urine (since this was sometimes altogether absent in uræmia), but on the amount of urea eliminated, as roughly indicated by the quantity of urine passed, and on the specific gravity, Dr. Griswold closed the discussion. He hoped, he said, that these cases of transient albuminuria would be carefully watched and followed up so that it might be seen what developments, if any, had occurred in the course of five, ten, fifteen, or twenty years.

The next order of business was the

PRESENTATION OF AN ACEPHALOUS MONSTER

by Dr. Daniel Brown. The labor was premature, coming on at the end of seven and a half months, and the delivery of the monstrosity followed that of a well-developed male fœtus, which lived until the following day. Dr. Brown stated that each separate fœtus had its own membranes and an entirely distinct placenta, the placentæ being attached at some distance from each other, and expressed the opinion that the acephalous fœtus was not dependent upon the other fœtus for its nutrition (as was ordinarily accepted in such cases), but that there was a direct continuity of circulation between the former and the mother.

The specimen was discussed by Drs. William H. Welch, J. Lewis Smith, and S. S. Purple, after which Dr. Austin Flint, Sr., made some remarks on

SCARLET FEVER

in connection with the paper read by Dr. Charles A. Leale at the last meeting of the Association on Scar-

latina in the Fœtus in Utero and in the Mother at the Ninth Month of Pregnancy. He said that personally he had seen no case of the disease occurring during pregnancy, but he had met with one instance of it occurring immediately after pregnancy. The patient, whom he saw in consultation with the late Dr. J. O. Stone, was twenty-eight years of age, and the child had been born two days when she broke out with the eruption of scarlet fever. The urine was slightly albuminous, and the lochial discharge and secretion of milk had ceased, but within twelve days she was convalescent. Two weeks afterward, however, he was again asked to see the patient, when he found that she was suffering from an attack of rheumatism accompanied by abundant albuminuria. She was then in a somnolent condition, and soon afterwards died. The child caught the disease from the mother, and therefore he thought it reasonable to suppose that the mother contracted it either just before or just after delivery. The infant recovered.

Dr. Flint then touched briefly on a few points which he said had occurred to him in looking over the notes of his cases of scarlatina. The first was the extraordinary vitality of the contagion, and one of the cases which he related to illustrate this was the following: A young lady, the daughter of a deceased physician formerly well known in New York, having entered one of the Protestant Sisterhoods was called upon to nurse a child suffering from scarlet fever. This she did for ten days, and after having aired the dress which she had worn during this time very thoroughly for several weeks she put the skirt of it away in a trunk. Eleven months afterward she wore the skirt for the first time after putting it away, and one week after she began to wear it she was herself attacked with acute diffused nephritis and pulmonary œdema, which proved fatal. The most thorough disinfection was, therefore, essential in every case of scarlet fever. He next spoke of the frequency of the occurrence of acute nephritis from the scarlatinal poison, the kidney complication in this disease being due not to cold, as was often imagined, but to the essential nature of the affection. He then mentioned the liability of cases to occur occasionally without eruption, and related one which he had met with in 1874, in which there was no eruption and no sore throat, but in which acute desquamative nephritis and also desquamation of the cuticle occurred. Having mentioned that there was some danger of death from heart-clot in scarlatina, and spoken of the good effects of cold baths in the disease, he concluded by a reference to the benefit of alcohol in the essential fevers in general, which he thought might, perhaps, be due to the fact that this agent acted in reality as a germicide, and by this action served to assist in sustaining the powers of the patient.

SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.

ALBERT N. BLODGETT, M. D., SECRETARY.

APRIL 9, 1884. Meeting called to order at eight o'clock, DR. R. T. EDES, chairman, presiding. A summary of the records of the last meeting was presented by the secretary.

DR. F. I. KNIGHT read a paper on the

LARYNGEAL COMPLICATION OF PULMONARY PHTHISIS,

dwelling especially on those which are considered almost pathognomonic, that is, those of infiltration or ulceration, or both these processes combined. He described at some length the laryngoscopic appearances of these lesions, and said that while they usually followed the pulmonary disease in order of development they probably preceded it in exceptional cases. The diagnosis was usually not difficult, but in doubtful cases anti-syphilitic treatment should be tried.

The prognosis was undoubtedly bad, but in some cases the laryngeal manifestation entirely disappeared. These cases afford a strong argument against the universal theory of tubercular infiltration.

In regard to treatment, Dr. Knight said that a mild climate, or even a warm, moist one, seems to suit these cases better than the cold, dry air of high elevations, which was so beneficial to cases of incipient disease of the lungs alone. Semi-solid food, taken cold, as a rule, suits best.

Judicious local treatment not only makes the patient infinitely more comfortable, but also in certain cases apparently brings about an arrest of the local disease. The old plan of cauterizing these ulcerations was bad. The whole local treatment of tissues so feebly nourished should be very gentle. In the first place the mucous membrane should be kept as clean as possible by the use of alkaline sprays. Weak astringents may be added or used afterwards. Carbolic acid in weak solution and iodoform do good in some cases. When there is much congestion and swelling, the frequent use of finely powdered ice was advised. Scarification does no good, but rather harm, unless there is a translucent œdema. Cutting into a small-celled infiltration only makes troublesome cicatrices. The careful passage of bougies into the œsophagus sometimes gives relief by producing absorption or diminishing the great irritability of the mucous membrane. Morphia powders, combined with sugar or starch, blown into the throat an hour before the principal meal, often give great ease in deglutition. Mild vapors of volatile substances like the oil of pine may be very grateful.

Tracheotomy may be necessary to avert asphyxia, but experience has not sustained the theory that cure of the laryngeal disease is facilitated by the rest to the organ secured by an earlier performance of this operation. Brushes, sponges, and all rough methods of making applications to the larynx should be, as a rule, avoided in this disease.

DR. CUSHING stated that he had very little to add in the way of therapeutics to the admirable suggestions contained in Dr. Knight's paper. A consideration of the pathological condition of the tissues surrounding tubercular ulcers, crowded with imperfectly developed small cells, was sufficient to make any attempt at healing them hopeless. In hospital out-patient practice and where the smell of iodoform was not objected to he had found the insufflation of that substance, powdered and mixed with one half its bulk of gum arabic, to be of great relief. The friends of the patient could easily learn to blow it on to the larynx without any mirror, for if a curved powder blower were steered beyond the epiglottis it was easy to diffuse the powder with tolerable accuracy over the diseased surfaces, and even in time the patient could learn to receive it in in-

spiration so that a part would come into the trachea, which was often inflamed and ulcerated.

A mixture of morphine in glycerine made pretty strong, so that ten drops would be a dose, and this applied with a spoon to the back of the tongue and allowed to trickle down over the larynx, frequently gives great relief.

Dr. Cushing had little respect for the operation of tracheotomy as a means merely of prolonging life in these cases, believing that when bad enough to cause death it was a kindness not to interfere in such hopeless cases; something might at times be said for the operation when required for relief of pain.

Dr. Cushing, by request, exhibited some of his microscopical preparations of tubercular larynges, showing how the small cells are first deposited along the tracks and at the forks of the smallest vessels; then the swollen mucous membrane of the infiltrated larynx was shown crowded with small cells, which in the neighborhood of the ulcers were so thick that no other tissue was discernible. At the edges of the ulcers it could be easily seen that the agglomeration of small cells had rendered the part incapable of self-support, and that increasing numbers when newly formed must swim off as pus or keep together as best they could in granulations or badly-nourished vegetations, the origin of some of which was demonstrated. Some sections of the trachea showed a precisely similar process there; the nutritive support of parts of the cartilage of the rings being cut off the part dies and is finally thrown off, leaving a deep "punched" ulcer, more or less covered with weak granulations.

Dr. Cushing during his remarks spoke of the fact that cases of tubercular disease of the larynx frequently occur when the most careful examination can find no disease of the lungs until long afterward, and although theoretically it has been maintained that such trouble in the larynx must be secondary to disease in the lungs or cheesy deposits elsewhere, yet practically the throat symptoms are often sufficiently pathognomonic when no disease of the lungs can be detected, and thus constitutional treatment can be commenced or change of climate advised at an early date of the disease, although with poor chance of success. He suggested that according to modern theories such cases of apparently primary laryngeal tuberculosis might easily be such in reality, being caused by direct infection from particles or bacilli in the air inspired.

Dr. Hooper remarked that he had been much interested in the paper, and agreed with the reader in the importance of always obtaining confirmatory evidence of disease in the lungs, and a careful history of the patient, before making a diagnosis of laryngeal phthisis. We meet with the diseases in the larynx in more than one variety, and the appearances are so different in the different stages of each variety that a positive diagnosis cannot be made without undoubted signs of chest lesion. In fact, in all the ulcerative processes of the larynx, whether due to syphilis, carcinoma, lupus, or diseases of the lungs, a detailed history of the case, and evidence of disease in some other part of the body, is necessary before we can decide upon the exact nature of the destructive process. Even if we followed the plan of Fränkel and others, and, in doubtful cases, wiped off some of the discharges from the interior of the larynx and found therein the bacilli peculiar to tubercular disease, we would then only be justified in eliminating with certainty syphilis and carcinoma; but whether we had to do with lupus, tuberculosis, or even leprosy, would still be an open question, unless, as already stated, we discovered other manifestations of one of these tubercular diseases in a different region of the body.

With regard to the question as to tuberculosis occurring primarily in the larynx, Dr. Hooper thought that any one who accepted Koch's discoveries must believe that such could be the case. If the disease in the larynx arises from the presence of the tubercle-bacillus in the sputum coming from the lung, why should not the same specific parasite when inhaled produce tuberculization of the tissues, provided always, of course, that the laryngeal mucous membrane is in a proper condition to receive it, and there is a hereditary predisposition on the part of the individual.

Dr. T. A. DeBlois said that often a great amount of comfort may be derived from scarifying the ary-epiglottic folds in those cases which are accompanied by much swelling, so that the epiglottis cannot properly close, and the patient is constantly choking from particles of food or drink which enter the air-passages with each act of deglutition. He has never seen any undesirable result follow this procedure. He never has observed ulceration of the cicatrix in these cases. In two cases he has seen laryngeal ulcerations heal under the use of iodoform, but in each case they broke down again after a few weeks. In one case in which the patient had been able to take no solid food for months, by the use of iodoform he was able to resume solid food for another full month. No other known form of treatment has ever accomplished more favorable results.

Dr. DeBlois showed an improved form of powder-blower for laryngological purposes.

Dr. W. J. Otis showed a powder-blower of a pattern originally brought from Vienna, but upon which he had adapted improvements which facilitated its manipulation and added to its usefulness.

In connection with the use of iodoform in tuberculosis of the larynx, Dr. E. W. Warren stated that he was working in Schrötter's wards in Vienna at the time when this became the regular treatment. Before this about one fourth of a grain of morphia was blown in. The improvement was very marked, and though not recalling that he saw any ulcers entirely heal, there was great diminution of infiltration, and the pain was less than under the morphia.

Dr. J. W. Farlow remarked that he had seen laryngeal ulcers heal, at least temporarily, in dispensary practice, under the use of iodoform. A gain of six or eight weeks is a great thing to these poor patients. Often the larynx is diseased for a considerable time before any disease of the lungs can be detected.

Dr. Bowditch agreed with the general tenor of the remarks of Dr. Knight upon the very great value of topical applications in diseases of the larynx, whether connected or not with pulmonary complications. But Dr. Bowditch could not wholly condemn the use of the nitrate of silver as injurious in these cases. It is well known that the late Dr. Horace Green, of New York, published nearly forty years ago a volume [1] the object of which was to convince the medical profession that nitrate of silver applied at times in a strength of thirty to forty, or even eighty, grains to the ounce of water,

[1] A Treatise on Diseases of the Air Passages. . . . Chronic Laryngitis, Clergyman's Sore Throat, etc. New York and London: Wiley & Putnam. 1846.

might be applied not only without danger to the larynx, but at times with great relief and final cure in some of the most obstinate and long-continued cases of laryngeal disease. Dr. Green also applied the solid caustic to specially enlarged follicles in the throat. Dr. Bowditch, however, had gradually given up the nitrate of silver for the liquor iodinii compositus, as the latter seems more agreeable to the patient and is equally efficient. Dr. Bowditch, moreover, without employing the laryngoscope, for his powers of sight prevented it, had always used a fine camel's-hair brush. With this he was sure that he could touch the vocal cords, often without the least choking. He knew so because the voice improved *immediately* in certain acute cases, and patients were cured after a certain number of such applications, made usually three times a week, and gargling with alkaline or other fluids three times daily. Dr. Bowditch found all spraying and powder blowing objectionable because of the choking that is often produced by them. Moreover, an expensive apparatus is needed, whereas the brush is a simple apparatus which every general practitioner can and ought to have.

There is, however, some art needed in making the application. One case that happened soon after commencing the course of topical applications had taught Dr. Bowditch that the operator must always be sure that the patient has *drawn a full breath, and is about to expire.* Let the vocal cords be touched *at that moment* and no spasm will occur. Let, on the contrary, the touch be made at the instant of inspiration, and violent results may occur. In the case above alluded to, and in which this blunder was committed, the patient threw himself upon the floor, and for a time *seemed* choking. No evil resulted, but a very great discomfort, which latter should be avoided if possible. In addition to the above rules Dr. Bowditch is accustomed, before treating the larynx, to make an application to each tonsil and to the back of throat, allowing the patient to breathe in the intervals. In this way the patient will be gradually led to believe that the final operation will be equally slight. It usually causes *no trouble*, except heat in the parts, although the patient feels that the operator has "touched the spot." Often a clearer voice and ease in speaking will be apparent in a few minutes.

Dr. Bowditch would dwell upon the various points in this simple operation, because each one is important for the *comfortable* performance of it.

Any discussion of the subject of laryngeal phthisis brings up a great number of important questions: What do we know about tubercle at present? How may we recognize tubercular from other forms of ulceration? Each of these single topics would form an inexhaustible subject of investigation and discussion.

DR. KNIGHT thought that Dr. Bowditch's method of applying medicines was a very good one, and would undoubtedly be a safe one to follow. There can be little doubt that tuberculous ulcers may sometimes heal, and the enormous swelling and other symptoms may quite disappear. Unquestionably this conduces greatly to the patient's comfort for a part and frequently for the whole remaining period of life. In regard to the possible arrest of the laryngeal disease three remarkable cases came to his mind at the minute. In all three the swelling of the cartilages was very great, the ulceration well marked, and the dysphagia distressing. There were positive signs of pulmonary disease in the first two, but not in the third. The swelling and ulceration almost entirely disappeared, and deglutition was relieved in the first two, but the patients died, one with symptoms of meningeal tuberculosis. In the third the signs and symptoms disappeared, with the exception of slight swelling of the epiglottis, and slight loss of substance in one vocal cord, and the patient has remained well, without any tubercular symptoms in larynx or lungs, for a year.

DR. J. V. MOTT, of New York, asked the reader if he had observed the effect of iodide of potassium internally in laryngeal phthisis? to which DR. KNIGHT replied that he had seen no beneficial result from its employment except in mixed cases or those which were undoubtedly syphilitic.

DR. MOTT remarked that this medicine was much used in the Metropolitan Hospital in New York, but the character of the cases is often very difficult to determine, as syphilis is frequently present.

In reply to a question as to the utility of general treatment and the results to the patients, DR. KNIGHT replied that hygienic and other appropriate methods of treatment should be diligently pursued in all these cases. The value of topical applications is much enhanced by a generally invigorating treatment for the whole system.

DR. G. L. WALTON read a paper upon

HYSTERIA AS AFFECTED BY REMOVAL OF THE OVARIES.[1]

DR. JOHN HOMANS spoke as follows: I think this operation cannot yet be definitely judged or accurately valued. I consider it to be still on trial. Many successful cases are reported, and others which are not favorable. Alienists and psychologists are divided upon this subject, some recommending the operation in selected cases, while others are not friendly to it under any circumstances. The removal of the ovaries should be thought of in relation to painful menstruation, and consequently in those conditions which depend upon or are induced by painful menstruation. In skillful hands the operation of ovariotomy and the other more common operations of abdominal surgery are no longer so dreaded as they were a few years ago, and the results of ovariotomy to-day are equally as favorable as those of capital operations of the extremities. Abdominal surgery is different from other surgical procedures, and cannot be taught; it must be learned by observation and experience.

Thus far I have operated upon three cases of the kind to which attention is directed in the paper of Dr. Walton. The first patient was a lady twenty-two years old, very bright and intelligent, highly educated, and thoroughly refined. Menstruation had always been irregular and painful. As the disease proceeded the patient first became hysterical, then gradually grew to be destructive, and finally became insane. It was thought that removal of the ovaries might have a beneficial effect, and the case was first brought to my notice by her friends, who sought my opinion in regard to this means of relief. There was at that time great tenderness in the left iliac region with rigidity on touching the part. She had already spent one whole year in bed at her home, and had passed a year at the Adams Nervine Asylum. She had been the frequent subject of gynæcologists and of specialists of various kinds. Finally she was placed in an insane asylum

[1] See page 529 of this number of the JOURNAL.

and was kept quiet by means of morphia. The pain was still present in the left side and much worse at the menstrual epoch. At such times the application of leeches to the *os* generally afforded some relief, but the case was gradually becoming worse and it was feared that her insanity would eventually become chronic.

In March, 1883, I removed both ovaries, with the Fallopian tubes. The patient did perfectly well and made a good recovery from the operation. Soon she began to experience relief from the old distress, and the iliac pains entirely left her. Then the headache diminished, and she became again a bright, intelligent, and perfectly sane person. She began to write, and furnished considerable manuscript for one of the daily papers. Finally her correspondence was intercepted by the family, and it was found that she had resumed the use of morphia, using the money earned from the newspapers to surreptitiously purchase the drug. On being reasoned with she promised to give up the morphia, which she did by gradually diminishing the dose until for months she has taken none at all. On examination the uterus was found to be in an infantile condition, about half the size of the thumb. From this time no unfavorable symptoms have shown themselves, and the patient and her friends consider the result as very successful.

My second case was a young lady who has had a somewhat celebrated history, from the fact that the disordered mental condition had been of some years' duration, and was of a very striking character. This patient was the subject of a scientific essay by Dr. W. B. Goldsmith, under the title of A Case of Moral Insanity, in the *American Journal of Insanity* for October, 1883, and a few extracts from her history as given by Dr. Goldsmith will clearly set forth her condition. He says: —

"The patient is a girl eighteen years old, rather short and small, but of well-knit muscular figure, and very active and strong. Her head is fairly well formed, though slightly inclined to the bullet pattern; her expression amiable and bright, and her general appearance calm. In her seventh year she had a severe attack of scarlet fever followed by a marked change in her mental condition. She became easily excited; seemed unable to apply her mind, and though apparently not malicious, could not be made to obey. Her father committed suicide at about this time, and this appears to have been the first occasion when she seems to have completely lost self-control. Soon after this she was sent to school, where she caused much trouble in various ways, and the teacher declared she spoiled the discipline of the entire school. After this she became subject to violent paroxysms of temper in which she would scream and throw herself about and break furniture and tear clothing. When between eight and nine years old, she was found naked bathing with some boys, and at this time admitted that she had frequently indulged in sexual dalliance with boys older than herself. She was now placed in various "Homes," from each of which she was dismissed on account of her violent and destructive paroxysms, and because she could not be made to observe any rules or regulations. She finally was placed in the Hospital for the Insane at Taunton, Mass., when nine years old, and there remained four years. No intellectual impairment was there detected in her, but she was thought to be in a condition of moral insanity. Dr. W. H. Gage wrote of her, 'she was an extremely difficult patient to manage.'

"From the Insane Hospital at Taunton she was removed to a similar institution at Worcester where she remained about twenty months, whence she was removed by her friends contrary to the advice of the hospital authorities. She remained quite well for four months, when on some trivial occasion she became much excited and leaped from the roof of a veranda, and was found screaming and maniacal on the walk below. The mania lasted two days, when she was placed in the Lunatic Hospital at Danvers. At this time her attacks of violence were generally induced by some slight disappointment or irritation, and would commence by attempting to destroy windows, pictures, or anything fragile. She was very violent toward her attendants, striking them and tearing their clothing and hair in a most vicious way. She has shown violence to every attendant with whom she has been for any length of time. Since her admission to the asylum at Danvers she has taken a variety of drugs, and exhausted the list of punishments and rewards practicable in a hospital for the insane. She has been kept thoroughly under the influence of bromides for weeks together; and the same is true for a less time of chloral hydrate; she has taken iodide of potassium, and has been overpowered by hyoscyamine; she has battled with various forms of mechanical restraint, and has demolished many; has tried every grade of ward, from the most violent to a parole ward where she came and went at will, and all without any perceptible injury or advantage."

I operated upon this patient last July, and removed both ovaries together with the Fallopian tubes. The wound healed by first intention, and she returned home in four weeks, and has been at home ever since. She has appeared to be perfectly well since the operation. Not a drop of menstruation has appeared since the ovaries were removed. Dr. Rowe has expressed the fear that a relapse of the mental disease might recur in these cases even after one or two years. In this case any hæmorrhage seemed to be a sufficient cause for a paroxysm, and the menstrual exacerbation was thought to be aggravated by the fact that it was of hæmorrhagic character, and the removal of the ovaries seemed to be beneficial in the way of preventing this recurrent loss of blood.

The third case was not a suitable one for this operation. The mental disease was of ovarian origin, coming on suddenly soon after marriage, and might, perhaps, have been benefited by an operation at an earlier date. There was undoubtedly commencing dementia before the ovaries were removed, and the patient's condition has become steadily worse from that time. The wound healed by first intention, and not a drop of menstruation has appeared since that time. The patient has become very violent and destructive, and has made dangerous attacks upon her attendants and upon other patients. She destroys her clothing, and has become filthy, passing her dejections in bed or in her garments. In this case removal of the ovaries has not benefited the patient, but the case has probably progressed exactly as it would have done if nothing had been attempted.

It is of no use to remove the ovaries by the vagina, but if the operation is to be done at all it should be by the abdominal incision, and the tubes should also be removed, when a much more favorable result may be expected.

Of these three cases the first may be classed as one

of hystero-mania, the second as one of pure hysteria, and the third at present as advancing dementia.

DR. CUSHING inquired who it is that gives consent to a capital operation when this becomes necessary in an insane patient.

DR. HOMANS replied that the consent of the guardians or next friends must in all cases be obtained, and also the consent of the patient. Few patients to whom this operation might be expected to prove of benefit are so insane as not to be able to understand and consent to its performance.

DR. ROWE stated that he had seen many cases of each of the diseased conditions mentioned by Dr. Homans which have exhausted all the resources of asylums, but he had never thought of ovariotomy as a means of treatment. This should be henceforth taken into more careful consideration. In all capital operations the consent of the natural or constituted guardians of the patient as well as his own should first be obtained.

DR. PUTNAM remarked that he had had no experience in this method of treatment of insanity. The operation would seem to commend itself even in cases in which the ovaries are not diseased. In many cases in which nervous symptoms are prominent the cure may be aided by judicious control of these functions. In ovarian troubles it may be useful to remove the periodical stimulation of these organs. In many instances of trephining, the nervous symptoms have been benefited or entirely relieved, when no fracture was found, no depression of bone existed, or any other evident mechanical interference with the functions of the cerebral structures could be anywhere observed. In like manner the supra-orbital nerve is cut in cases of spasm of the eyelid, followed by relief to this condition. It is thought to act by removing one source of irritation to the motor centres.

DR. HOMANS added that removal of the ovaries with cystic degeneration of their structure is sometimes followed by insanity. This operation is still young in its relation to mental disease, and is liable to abuse. It should be especially guarded in its application to these unhappy cases, and should be done only as a last resort. In one case in which the ovaries were removed per vaginam the condition of the patient was much worse than before the operation. If the tubes had been taken too, the result might have been different. Such a person ought not to be allowed to breed, and if anything is attempted, both ovaries and both Fallopian tubes should be removed, and thus the utmost possible good be accomplished for the patient.

In one case of double ovariotomy the patient has flowed regularly and irregularly ever since that time. Removal of the ovaries does *not* cure dysmenorrhœa. This important fact should not be forgotten in advising any operation short of complete extirpation of both ovaries and Fallopian tubes.

DR. J. J. PUTNAM said he had had no experience in the use of Battey's operation, but was quite prepared to believe that its effects might be beneficial both where the ovaries are diseased and even in some cases where they are not. The favorable action of the treatment in the latter group would probably be due to a restriction of the activity of the nervous system within narrower bounds.

AN ANTISEPTIC ABSORBENT PAD.

DR. FARLOW exhibited an antiseptic pad which had been devised for the benefit of ladies while traveling or while menstruating and after parturition. It is made of coarse cheese cloth, and is filled with borated absorbent cotton, and can be easily prepared by any one. This pad is for sale by druggists at one dollar a dozen.

SENILE GANGRENE.

DR. FITZ showed a series of specimens from a case of senile gangrene operated on by Dr. Warren, and reported upon by him at a meeting of the Society for Medical Improvement, March 24, 1884.[1] No untoward symptoms occurred till within twenty-four hours of death, and the appearance of the wound was favorable till that time. At the autopsy the edges of the wound were firmly adherent throughout the greater part of its circumference, and there was no discoloration or swelling. Both popliteal and anterior tibial arteries were found calcified just below the popliteal space, and both contained thrombi. Venous thrombosis extended upwards from the amputated stump into the femoral vein, terminating just below Poupart's ligament. The thrombus was pale-red, friable, and softened centrally.

Several branches of the pulmonary artery of both lungs, at least a line in diameter, contained reddish-gray thrombi, and at the base of the right lung there was a peripheral nodule of hæmorrhagic infarction of the size of a walnut. Both lungs were œdematous, and the right pleural cavity contained four ounces of opaque pink fluid, the pleural surfaces being besmeared with a thin yellow membrane. There was no necrosis of the pleura.

The spleen was more than twice the usual size, intimately adherent to the abdominal wall and to the omentum. It was dense and heavy, the surface irregularly depressed and nodulated from the presence within the organ of numerous nodules of anæmic necrosis, varying in size from that of a plum to that of a hazelnut. These patches were often porous on section from the presence of numerous cavities containing a relatively clear fluid. Between the necrotic patches the spleen was indurated and reddish-gray in color, while scarcely a trace of splenic structure was to be found normal in color and consistency. A circumscribed patch of thickened intima of the aorta was present, which included the origin of the cœliac axis and the superior mesenteric artery. The former was entirely occluded by fibrous tissue, and the calibre of the latter was diminished one half for a short distance from the aorta, and then was considerably dilated.

The hepatic branch of the cardiac axis was dilated, the splenic artery was narrowed, its walls thickened, and its cavity completely obliterated throughout its entire course by means of an adherent, dark-red, firm thrombus. The splenic vein was also obliterated by a reddish-gray, centrally-softened thrombus, which was continued into the portal vein. The trunk of the latter was filled with the thrombus which extended into the hepatic branches of this vessel.

Peripheral portions of the liver showed a nutmeg appearance, and a nodule of anæmic necrosis the size of a plum was found.

There was a varicocele of the right side, the spermatic vein entering the right renal vein. A moist, dark-red, distending thrombus was continued from the immediate vicinity of the testicle into the right renal

[1] See Boston Medical and Surgical Journal, 1884, xv., 349.

vein, whence it extended towards the inferior vena cava as a thrombus the size of the tip of the little finger.

The chief interest of these specimens lay in the evidence of long-standing serious disease without striking symptoms at the time of the operation; also in the comparatively slight alterations of the liver, despite the obliteration of the cœliac axis and the obstruction of the portal vein. Embolism of the pulmonary artery was to be regarded as the immediate cause of death, while the thrombosis of the renal vein was presumably of marantic origin, and might have been not above twenty-four hours' duration.

Three varieties of thrombi were present, each independent in origin from the others, and neither having given rise to recognizable symptoms till the day before death, when the occurrence of pulmonary embolism was suggested. The stomach gave evidence of extensive softening of the mucous membrane, with putrefactive emphysema, although neither condition was associated with the usual favoring circumstances.

ACTINOMYCOSIS.

DR. W. F. WHITNEY showed a specimen of actinomycosis, the first ever exhibited in New England.[1] It occurs in horses, cattle, sheep, etc., and has been frequently observed in Europe. This specimen was from a heifer, and was sent to Professor Lyman, of the Harvard Veterinary School, and by him referred to Dr. Whitney. The disease was located on the lower jawbone, and was as large as the two fists. The character of the growth is fibrous, and shows large numbers of patches of a yellow color, which contain lime salts, and also masses of the parasitic growth.

DR. FITZ stated that this disease has been observed in isolated cases in the western part of the United States, but that this is the first case reported in this vicinity. The disease can be communicated to man from the domestic animals. Usually the jaw is the part first attacked, and from this point the disease may extend to the thorax, spine, and elsewhere. The origin of the fungus is not yet definitely known. It has been thought by some to enter the organism by means of defective teeth.

Recent Literature.

Principles of Theoretical Chemistry, with Special Reference to the Constitution of Chemical Compounds. By IRA REMSEN, Professor of Chemistry in the Johns Hopkins University. Second edition. Thoroughly revised and enlarged. Philadelphia: Henry C. Lea's Son & Co. 1883.

This book is divided into two parts. The first part is devoted to a general discussion of atoms and molecules. Chapter I. treats somewhat in detail of Dalton's investigations, the atomic theory, and the methods which we possess for the determination of atomic weights dependent upon purely chemical processes. Chapter II. treats especially of Avogadro's hypothesis, and its application in the determination, primarily, of the molecular weights of compounds and elements, and, secondarily, of atomic weights. Chapter III., the relationship between specific heat and atomic weight. Chapter IV., the schemes of D. Mendelejeff and Lothar Meyer for showing the connection between the atomic weights and properties of the elements. Chapter V. is on the valence or atomicity of the elements. The second part treats at considerable length of the constitution or structure of chemical compounds.

The book has been thoroughly revised, the most noticeable changes being found in the chapters on valence and constitution. A short chapter on the physical methods for determining the constitution of chemical compounds has been added.

In his preface the author says: "I have endeavored to discuss in an impartial way, as objectively as possible, the principal hypotheses which at present play important parts in the science of chemistry." "My object has been to point out as clearly as I could the exact connection between the facts known to us and the hypotheses."

We find in this book the most impartial and satisfactory discussion of the above subjects which we have seen, and we cordially recommend it to those who wish to familiarize themselves with the fundamental hypotheses connected with the science of chemistry, and with the facts which suggest these hypotheses.

New York and Brooklyn Formulary of Unofficinal Preparations. Published by a Joint Committee of Delegates from the College of Pharmacy of the City of New York, the New York German Apothecaries' Society, and the Kings County Pharmaceutical Society. Publication Office: College of Pharmacy Building, New York. 1884. xii. 46 pages.

This is a collection of eighty-one practical formulas for such preparations of the so-called "Elegant Pharmacy" as appear to have established a claim to some recognition, and have survived out of the endless number offered to the medical profession. They are now respectfully submitted by the committee with the very reasonable request that physicians should abstain hereafter from designating the maker's name of any preparation for which a formula is found in this pamphlet, that thus both physicians and pharmacist may be sure to obtain uniform preparations, no matter where they may be dispensed. The preparations mentioned are fifty-two elixirs, ten emulsions, two extracts, one liquor, five spirits, six syrups, two tinctures, and three wines.

The universal use of such formulas would prove as beneficial to the medical profession in this State as they will in New York. B. F. D.

A Handbook of Therapeutics. By SIDNEY RINGER, M. D., Professor of the Principles and Practice of Medicine in University College, London. Tenth edition. 688 pages. New York: William Wood & Company.

This last edition of a valuable and widely read work differs very little from the previous one. The changes are few and of minor importance, among them are a short page on Eucalyptus, a rather longer mention of the salts of manganese, and the addition of a few paragraphs about salicine. In its present form this suggestive Handbook will doubtless continue to prove useful to a large number of physicians.

Medical and Surgical Journal.

THURSDAY, JUNE 5, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

THE "TAXATION" THEORY OF EXPERT TESTIMONY.

MANY are the remedies which have been suggested for the obvious failures and defects of our system of expert testimony. But it is difficult to see what improvement is to be looked for in the value of such testimony either from a scientific point of view or as an instrument to the furtherance of justice from such a position as that which is taken by Mr. Rossiter Johnson in the current number of the *North American Review*. His theory is that the demand of the State upon the expert witness is to be considered as a species of taxation, and while no system of taxation has ever been devised which is absolutely equitable, yet that the levy by the State upon the capital of the professional man (that is, his time and his scientific acquirements) according to her needs, without compensation, is consistent with justice and equity. According to this view no distinction should be made, at least so far as concerns subpœna or compensation, between expert and ordinary witnesses. Both alike, together with the jurymen, are to give their services for the good of the State without recompense, or, rather, the nominal fee tendered is supposed to represent the bare cost of living for the time occupied, which sum the State is bound to exempt from her claim. The men who are called upon to serve in court, whether as jurors or witnesses, pay a varying tax according as their time and services are worth much or little. Only the day laborer is exempt; his tax is remitted to him in the form of a fee, and this simply because it is all he has to live upon, and the State cannot beggar him. The case is compared to the laying of the income tax in our late war. Incomes up to $600 were exempted from taxation on the ground that so much was necessary to subsist upon, but incomes over that amount paid the whole tax, which, therefore, fell very heavily upon the wealthiest people. So, during the conscription in our late war, men were enrolled for military service, with practically no compensation, because the country needed their aid. The day laborer received enough barely to keep him and his family from want, and no more was given to the ex-clerk, engineer, or lawyer who had been earning his one, three, or five thousand per year. In fact, in this case of urgency the tax was still more oppressive and arbitrary, for the conscripts gave not only their time but in many cases their limbs and lives; and each hundred men that were enlisted might know in advance that a certain number of them, on the doctrine of averages, never would come back.

All this is intelligible, nay, more, it is right, for under all government it must sometimes happen that the welfare of the individual should give way before that of the public, and we accept the parallel for jury service, suffrage, and such other universal duties of citizenship. If a man by chance witnesses a crime it is doubtless his duty to attend in court and give his evidence, though it may involve a loss of a hundred dollars in his business, for which he receives in compensation only the regular fee of fifty cents. To-morrow a part of the debt will be repaid to him in the discharge by his neighbor of a similar duty of good citizenship, and the chances are that not for many years, if ever, will he again be thrown into circumstances where such a duty will be placed upon him. True, if his calling is one which specially exposes him to the liability of becoming cognizant of crime (as does that of a physician) he must be prepared to meet this additional tax which society places upon him.

But here, it seems to us, the analogy ends. Beyond what, as a member of society, he sees and hears, the physician should not be held subject to this taxation of time and talents. A murder is committed. The physician was in no sense a witness to it, in fact, knew nothing about it. By reason of special training, opportunities, or advantages on his part, however, he is able to form an opinion which is of value in solving some problem connected with the crime. His opinion is, therefore, sought for the purpose of "furthering the ends of justice." Having once gone through the special mental drill necessary to forming and formulating such an opinion, he is still better able to do it a second time, and is, therefore, even more important in furthering the ends of justice, until finally his whole time may be taken up with this sort of work.

Let us be impartial in this matter. Whatever claim the State has upon the physician as a good citizen, to "further the ends of justice," by giving his time and labor in the elucidation of cases of which he was not personally cognizant, precisely the same claim exists upon judge and attorney, sheriff and constable. They also are bound to give their best services whenever asked to further the ends of justice. But the State has, and with good reason, made these officials its employees, because they possess qualifications and opportunities above those of the average citizen for the detection of crime, and if these qualifications were to be "taxed" instead of recompensed, a gross injustice would be done to a particular class of men. For exactly the same reasons should the expert witness receive compensation from the State for the equally valuable service which he renders her. Whether this official shall be a member of a permanent board and be paid an annual salary, as in some of the countries of Europe, or whether as merely a man of recognized and approved authority in his specialty, whatever that may be, he is summoned to give his assistance in every separate case where it is needed, are of minor im-

portance compared with the point that he shall be summoned when required by the court and paid by the State, and hence be primarily independent of either side in the dispute. The tender of a fee to the expert witness by either of the contestants could then be held as equivalent to the offer of a bribe. Then might the disgraceful counter-swearing of professional men be at an end, and the white light of science fall upon judicial inquiries, unstained by the media of opposed interests.

The comparison has been happily made of the expert witness to the interpreters sometimes required to translate evidence in court. The interpreter should certainly be not in the employ of either party, but of the court, and sworn to give a true and correct interpretation of the evidence. But this is not the point of the analogy with which we are now especially concerned. The evidence may be in French or German, and interpreters are comparatively easy to find. But again, it may be in Chinese or Persian. The court learns of a man who happens to know the foreign tongue. The man is summoned from his business. Shall he be "taxed" his time and labor, and if he proves a good interpreter be summoned again and again whenever his services are needed, irrespective of his personal interest or concern in the given case? or shall he be made an employee for the time being? The interpreter of science has a harder language to translate than any human speech; and the vocabulary of his hearers into which that unknown tongue must be rendered is often a very limited one. Shall he whose task demands a higher intelligence and more patient toil than that of the common interpreter be treated less equitably? To our minds there is a very important sense in which the claim to such a man's service as a right of taxation does *not* "further the ends of justice."

A WORD FOR MILITARY DRILL IN SCHOOLS.

"It is highly probable that those parents who, through mistaken notions of education, permit their children to grow up ignorant of self-surrender, discipline, and restraint, are encouraging in them the tendencies to excess which in later life may issue in insanity. It is indeed a patent fact that the power of self-control is less cultivated at present than formerly. Our forefathers held many hard and barbarous beliefs, but there was one belief of theirs which we should have done well to retain, namely, the conviction that serious and prolonged discipline is necessary to the building up of a sound and self-sustaining manhood. In these days the last lesson imparted is that of obedience, yet it is certain that they who cannot obey will never know how to rule, and that without self-control the finest natural abilities may be worse than wasted.

"When the tendency to insanity is the effect of new ideas upon sluggish mentalities, which are confused rather than enlightened by the impact, it is probable that nothing can be done. In such cases Nature's law of the survival of the fittest must operate, and such as are incapable of improvement must perish. But with regard to the stronger natures that tend to excess because of defective training, it is not useless to speak words of warning. Nature will be avenged for violations of her laws, and those who exhaust their limited stock of vitality in youth and middle life will be denied the restful old age to which they vainly look forward. Parents who think it philosophical to withhold all discipline and training in self-control from their children will do well to reflect that, far from fitting them for an ampler manhood and womanhood by these means, they are preparing them for disaster, misfortune, and failure, and depriving them of the most indispensable defense and protection against the distracting influences of our fast and feverish modern life."

Such are the expressions of one of our leading daily papers. It is evident that the youth of to-day have a very different training from that received by the generation now passing off the stage. Our city streets show a mob of half-grown boys who are growing up without restraint at home, without the restraint of a business apprenticeship, and with an ever lessening reverence toward God and respect toward man. These are the extreme instances of the universal relaxation of discipline which is only too evident in all classes of society. The entire abolition of corporal punishment in public schools is a sign of the change in public sentiment in the matter.

The exhibitions of military drill in the higher public schools which have taken place in Boston during the past week deserve a passing notice in connection with this subject.

In this military drill is found, for a portion of the rising generation, some slight counterpoise to all this license and lack of discipline. The drill occupies but a small amount of time, it is not severe, but it does teach boys to obey, and that on the instant, and later to command. One might well question if it might not be more beneficial if it were more severe. We doubt if any officer is ever "broken" for failure to maintain proper order. To one who has experienced the severities of West Point or Annapolis the discipline must seem very lax, but, on the other hand, to one who looks with apprehension at the consequences to be feared from universal lawlessness it offers at least a little comfort.

A VERDICT OF MANSLAUGHTER AGAINST AN IRREGULAR PRACTITIONER.

The trial of "Dr." Franklin Pierce, an irregular medical practitioner of Worcester, Mass., occurred before the Superior Court in that city two weeks ago, on an indictment charging him with manslaughter in causing the death of Mrs. Mary A. Bemis, of West Boylston, in January, 1883, by the use of kerosene oil. The case excited considerable interest. The husband of the deceased testified that during his wife's illness Dr. Pierce said at various times that she had ulceration of the womb, gastro-bilious fever, typhoid fever, water

about the heart, and erysipelas. He ordered that the patient's temperature be taken every hour with an ordinary house thermometer, and that a record of her pulse be also kept, so that he could report progress of the case to a dean of some college in Boston. When he discovered the symptoms of erysipelas, one week before she died, he ordered the patient packed in kerosene oil from her neck to her toes, so as to draw out the disease. Cloths were saturated in oil, wrung out, and then laid on. She complained of intense burning pain, and the treatment was discontinued after two and a half hours. Dr. Pierce was sent for. He ordered the kerosene treatment renewed, this time by pouring oil on the cloths without removing them. This treatment was continued for thirty hours or more, when he ordered the cloths removed. It took three hours to remove the cloths, and large patches of skin came off with them. The next day Dr. Pierce presented a bill for $180 for consultation fees in Boston and $45 for surgical examinations. His services were dispensed with the following day, and other physicians called in, who said the patient was past recovery.

The testimony of the nurse showed, in addition, that after the first application of the kerosene the skin hung in strings from the patient's body. When the doctor ordered a second application he forbade the nurse to use sweet oil to allay the pain.

Dr. J. Marcus Rice, the medical examiner who conducted the autopsy, said the woman's epidermis was two thirds burned away; that the true skin was destroyed in several places, and that in some spots the muscles were exposed. He found no sign of pericardial effusion. In his judgment death was caused by the destruction of the epidermis by the use of kerosene. This opinion was confirmed by other medical testimony. One physician who had treated Mrs. Bemis testified that pulmonary troubles and chronic diarrhœa would probably have ended her life soon, and kerosene packing only hastened death. In his opinion she might have recovered from the kerosene treatment but for her vitiated condition.

The defense opened, and put on half a dozen witnesses, who, under Dr. Pierce's direction, have used kerosene in a similar manner to that in this case for erysipelas, typhoid fever, congestion, typhoid pneumonia, and other diseases. All agreed that the treatment was highly beneficial to them. The defense also offered testimony to show that the husband had administered two doses of aconite to his wife, early in her sickness, of eight drops each.

The only witness in rebuttal testified that, under the prescription of the defendant, kerosene oil had been used on her son as a remedy for lung fever until it took off the flesh and laid the bone bare.

The jury were out ten minutes, and returned a verdict of guilty.

MEDICAL NOTES.

— The following have been chosen officers of the Middlesex East District Medical Society for the ensuing year: President, Dr. John O. Dow, Reading; Vice-President, Dr. Winthrop F. Stevens, Stoneham; Secretary, Dr. George E. Putney, Reading; Treasurer and Librarian, Dr. John O. Dow, Reading; Councilors, Dr. Arthur H. Cowdrey, Stoneham, Dr. Frederic Winsor, Winchester, Dr. Seth W. Kelley, Woburn; Nominating Councilor, Dr. Winsor; Censors, Dr. Charles C. Odlin, Melrose; Dr. William S. Brown, Stoneham; Dr. Daniel March, Winchester; Dr. Julius S. Clark, Melrose; Dr. Fred. W. Graves, Woburn; Commissioner on Trials, Dr. Francis F. Brown, Reading; Reporter, Dr. George E. Putney, Reading.

— Two new prescriptions for the treatment of warts are announced in the *Wiener Med. Blätter* (November 8th). One is the application of a piece of lemon peel which has been immersed for eight days in acetic acid three or four times renewed. The slice of peel is left on the wart until it dries, which it does in about nine hours, and this is repeated four or five times. The wart is then so much loosened that it can be removed by strangulation. The second mode of treatment is to insert a pin beneath the wart, avoiding the healthy skin, and then to heat the pin's head in a spirit-lamp. This causes the wart to become white and shriveled at once, when it is easily removed without any bleeding.

— M. Pasteur and his *collaborateurs* have announced to the French Academy that they can render all dogs absolutely proof against the effects of rabies by inoculation however the virus may be administered.

— In the *British Medical Journal*, February, 1884, page 281, it is noticed that in the statistics of the Caen Hospital only four cases of stone were admitted during fifty-nine years. In one the nucleus was a foreign body; in two the patients drank wine, *not cider*, which is the ordinary beverage in Normandy. Inquiries showed that stone in the bladder is rare in countries where cider is the chief drink. M. Denis-Dumont is said to have found the diuretic properties of cider most useful in cases of gravel, obesity, and some forms of gastritis.

NEW YORK.

— At the last meeting of the County Medical Society, held May 26th, Dr. Milton Josiah Roberts read a paper on The Treatment of Ankle-Joint Disease and the Mechanism of its Cure, and presented a patient cured without deformity and without anchylosis. A resolution, offered by Dr. J. A. Irwin, was adopted urging upon Congress the necessity of suitable legislation to secure a more efficient medical service upon ocean steamships in order to prevent the needless sacrifice of human life and the introduction of foreign infection, as far as possible, into this country.

— The free public baths were opened on the 1st of June as usual. There will be eleven instead of nine this year, two of the old ones having been sold, and four new ones built at a cost of $50,000. Six of the baths are located on the East River front, one at the Battery, and four on the Hudson River front.

— Nine graduates received diplomas at the com-

mencement of the Woman's Medical College of the New York Infirmary, which was held on Thursday evening, May 29th.

— Work has now been commenced on the Vassar Brothers' Hospital at Poughkeepsie. It will consist of three principal parts, — an administrative building and a pavilion on either side, — all of which will be two stories in height with high slate roofs. They will be joined by a one-story corridor with a spacious veranda. The buildings are to stand on a bluff, facing the west, and their extreme length, from the north side of the north pavilion to the south side of the south pavilion, will be 180 feet, while the extreme depth, from the front of the administrative building to the rear of the pavilions, will be 120 feet.

— The State Board of Health has just received from one of its inspectors a report which reveals a very unsatisfactory sanitary condition among the cattle at Blissville, L. I. In the stables of one firm, which were in a terrible state of filth and offensiveness, between four hundred and five hundred animals were found housed and fed on distillery swill and hay, and one case of pleuro-pneumonia was discovered. In another stable out of forty cows three were just dying of the disease, and there were five acute cases of it beside. All had been milked that morning, and the milk distributed to customers. An almost equally large percentage of cases of pleuro-pneumonia were also found at other dairies, and there is reason to suspect that diseased cows, no longer able to furnish milk, are slaughtered and the meat smuggled into New York and Brooklyn.

Correspondence.

GRADUATING EXERCISES AT BOWDOIN MEDICAL COLLEGE. MEETING OF THE MEDICAL ALUMNI, PORTLAND, JUNE 2, 1884.

Mr. Editor, — The attendance at the Medical Department of Bowdoin College varies from year to year but slightly from one hundred, and in the term which closed on the 28th of May was ninety-nine. A gratifying circumstance in this connection is that one third of these were graduates of colleges, nine New England institutions of learning having representatives in the class. Thirty-three candidates received the doctorate in medicine. In previous years the graduating exercises have been conducted with but little ceremony, though it has been customary to have an address from some man who had attained eminence in medicine, law, or theology, but this year the class arranged a programme of a more pretentious character, and set an example which will doubtless be followed by all their successors. The address was given by the Rev. Dr. S. G. Brown, professor of mental and moral philosophy in the college, formerly the occupant of the same chair at Dartmouth, and president of Hamilton. His subject was some of the relations of the medical profession to the complicated result which we call civilization, and he handled it in a manner which displayed a critical appreciation of the aims, duties, trials, and achievements of the educated physician. The large audience which filled Memorial Hall listened to the oration with great satisfaction and approval. A valedictory address was pronounced by Mr. F. C. Heath, who had been chosen by his classmates to represent them. It was full of bright points, and was admirably delivered. The diplomas were then presented, and the class sang a very appropriate ode, which was written by Mr. C. L. Barnes. The exercises were enlivened by excellent music furnished by an orchestra of fifteen pieces.

Last January there assembled at Waterville between twenty and thirty of the graduates of the Medical School of Maine in response to an invitation of Dr. Frederick C. Thayer, of the class of 1867. Though the institution had been in existence for sixty-three years, and had educated more than thirteen hundred physicians, there had never been an association of its alumni. On this occasion, however, such a society was organized, and Dr. Thayer, the projector of the enterprise, was very properly elected as its president. A constitution was adopted by which it is provided that any person on whom a degree in medicine has been conferred by Bowdoin College may become a member of the Society by signifying his desire to this effect in writing to the secretary, and paying one dollar to the treasury, provided his character and professional standing are satisfactory to the executive committee, which consists of all the officers. The annual meeting is to be held in the week of the graduating exercises at the School. In accordance with this rule the Bowdoin Medical Alumni Association met in Memorial Hall immediately after the newly-made doctors marched out with their sheepskins. Nearly one hundred were present, and this number would have been greatly augmented but for the severe storm which lasted all day. The President briefly addressed the society, congratulating it upon the auspicious beginning of the new organization, and expressing the opinion that the alumni owed a duty to the institution which gave them professional birth, an obligation which they could discharge in various ways. One, upon which he laid great stress, was the establishment of an alumni fund, contributed by the graduates of the School, and devoted to the advancement of medical education through the medium of this institution. The suggestions of the President were referred to a committee consisting of Drs. Horr, of Lewiston, Walker, of Thomaston, and Osgood, of North Yarmouth, which reported a general approval of them, but added that the matters were of so much importance that they could not be sufficiently discussed in a short time, and recommended the appointment of a committee which should be instructed to report on the subject at the next meeting. The report was accepted, and a committee was chosen composed of Drs. Horr, of Lewiston, E. M. Fuller, of Bath, and H. H. Hunt, of Portland. A constitutional amendment was adopted by which past and present members of the Faculty of the School may be elected to honorary membership. Those who have been instructors, who are not graduates of this School, and who are still living, are Dr. William Perry, of Exeter, N. H., lecturer on theory and practice in 1837; Dr. Corydon L. Ford, of Ann Arbor, Mich., professor of anatomy and physiology from 1864 to 1870; Dr. A. B. Palmer, of Ann Arbor, professor of pathology and practice from 1870 to 1879; Dr. Thomas Dwight, of Boston, professor of anatomy from 1872 to 1876; Dr. Robert Amory, of Boston, professor of physiology from 1873 to 1875; Dr. Thomas T. Sabine, of New York, lecturer on anatomy in 1871, and on surgery in

1872; and Dr. E. W. Jenks, of Chicago, professor of obstetrics from 1872 to 1874. These were made honorary members, as also were those present professors who are not graduates of the institution. The old list of officers was reëlected. They are F. C. Thayer, of Waterville, President; S. Laughton, of Bangor, first Vice-President; R. D. Bibber, of Bath, second Vice-President; C. D. Smith, of Portland, Secretary; F. H. Gerrish, of Portland, Treasurer. The executive committee was authorized to expend at their discretion such moneys as are in the treasury. Dr. A. J. Fuller, of Bath, delivered an address, after which the Association adjourned to the large dining room, on the ground-floor of the building, where a bountiful and toothsome banquet was spread. The newly-graduated class attended as guests of the Faculty. The dinner being disposed of, speeches, in response to toasts, were made by the acting President of Bowdoin College, by Dr. I. T. Dana, the senior medical professor, by Dr. Horr, President of the Maine Medical Association, and others.

The aged Professor Packard, who is acting President, gave a most interesting account of the beginnings of the medical department, the early professors in which were his personal friends. Those who knew Nathan Smith, John Doane Wells, and Parker Cleaveland as young men are not often seen nowadays; and it was a genuine treat to listen to this venerable man as he narrated incidents in the lives of the founders of the Medical School, telling the story with a simplicity and unconscious pathos which touched every heart. Dr. Dana spoke of the work the School is accomplishing in elevating the standard of education, and of the need of larger clinical opportunities, intimating that the institution should be moved as soon as possible to Portland — an opinion which is shared by almost everybody who is familiar with the circumstances of the case. Subscriptions have been raised for the erection of an amphitheatre for the Maine General Hospital, and there is no doubt that the Medical School of Maine will change its location from Brunswick to Portland as soon as a suitable building for its accommodation is put up and deeded to the College of which it is the medical department.

The first annual meeting of the Association is unanimously considered a great success, and the next is looked forward to with the pleasantest anticipations.

There are many alumni whose addresses are not known, and all who did not receive a circular invitation to this meeting are earnestly requested to furnish the Secretary with information as to their residences at their earliest convenience.

Prof. Burt G. Wilder, who has occupied the chair of Physiology for nine years past, has resigned, and Dr. Henry H. Hunt, of Portland, has been chosen lecturer for one year in his place.

Miscellany.

PHYSIOLOGICAL ALBUMINURIA.

THE growing opinion that albumen is more frequently present in the urine than was formerly believed, receives support from a recent thesis of M. de Chateaubourg,[1] in which observations are reported conducted chiefly upon healthy soldiers and children. The tests were made by several reagents, but especially with that of Tanret (double iodide of mercury and potassium strongly acidulated with acetic acid) employed according to the method of Professor Bouchard. These means are necessary for recognizing the small amounts of albumen often found, as, for instance, from .005 to .01 gramme of albumen to a litre of urine. The general results obtained by M. de Chateaubourg show that albuminuria is frequent in healthy people. For instance, in 701 examinations made upon persons in perfect health, albumen was found in 592 cases, giving a proportion of eighty-four per cent. The cases where there was a considerable quantity, that is, more than .03 per litre, were sixty-four per cent. In 169 cases even, the amount of albumen was more than .25 per litre.

The author concludes that this physiological albuminuria is variable and modified by many casual circumstances. Thus there were individuals who one day had .25 of albumen per litre and the next day had none. It is modified among other things by bodily fatigue, which markedly increases it, as could be seen in a body of soldiers, both in the number affected and the amount per man. Brain work also increases albuminuria, as was observed in a number of young men preparing for an examination. Digestion, if accomplished during repose, has no effect on the albuminuria. But not so menstruation and the generative functions. Cold baths were found to have a marked effect. Fifty-three men having taken a five-minute bath were found to have albuminuria to a man, but in varying degree. A preliminary examination had shown that sixteen of the men had no albumen when they got out of bed. The amount in the others was increased after the bath. Most of these men had albumen the next day but in much diminished amount. It is pointed out that this influence of cold baths has an important effect. For if it be admitted, as Semmola has long taught, that the repeated transudation of albumen through the renal filter may produce alterations in the renal epithelium, it would seem that bathing should be carried on only with great caution by persons having transient albuminuria, especially if it be easily subject to exacerbations.

THE FIRST DISCOVERER OF THE USEFULNESS OF KANGAROO TENDONS FOR LIGATURES.

WE trust that the name of a well-known physician of this city will not escape recognition under the disguise in which it appears in the following paragraph, which we clip from the *Australasian Medical Gazette*:

"In the *New England Medical Monthly* for June, 1883, Dr. Henry O'Marey, of Boston, is credited with the discovery that fibres of kangaroo tendons, antiseptically prepared, make the best ligatures and sutures for surgical purposes. We would call attention to the fact that Mr. T. M. Girdlestone, F. R. C. S., Eng., of Melbourne, is the surgeon who is really entitled to the credit of this discovery, and that, acting on his recommendations, these tendons have been for some seven years frequently used by him and other surgeons in Australia and England. He first exhibited tendons, prepared by himself, at a meeting of the Medical Society of Victoria, held on December 5, 1877, and called the attention of the profession to their usefulness, giving his own experience in their use."

Deaths reported 2496 (no reports from Cincinnati, Buffalo, District of Columbia, and Providence): under five years of age, 942; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 476, consumption 343, lung diseases 287, diphtheria and croup 116, diarrhœal diseases 98, scarlet fever 63, measles 62, typhoid fever 32, malarial fevers 29, whooping-cough 20, cerebro-spinal meningitis 18, small-pox 12, erysipelas 12, puerperal fever 12, typhus fever four. From *measles*, New York 20, New Orleans 18, Chicago 10, Philadelphia five, Baltimore four, Pittsburg and Milwaukee two each, St. Louis one. From *typhoid fever*, Philadelphia 12, Chicago, Boston, and Pittsburg three each, Nashville two, New York, Brooklyn, Baltimore, St. Louis, Lowell, Lynn, Holyoke, and Waltham one each. From *malarial fevers*, New Orleans 14, New York and Brooklyn five each, Baltimore and St. Louis two each, Chicago one. From *whooping-cough*, New York 11, Brooklyn and Chicago three each, Baltimore two, New Orleans one. From *cerebro-spinal meningitis*, New York and Philadelphia four each, Chicago and New Haven two each, St. Louis, Nashville, Fall River, Newton, Brockton, and Chicopee one each. From *small-pox*, New Orleans 11, Philadelphia one. From *erysipelas*, New York three, Chicago and Boston two each, Philadelphia, Brooklyn, Baltimore, St. Louis, and Charleston one each. From *puerperal fever*, Boston three, Brooklyn and Baltimore two each, Chicago, St. Louis, Milwaukee, Charleston, and Lowell one each. From *typhus fever*, New York four.

Three cases of small-pox were reported in St. Louis (these three cases were from East St. Louis, Illinois, and taken to the hospital at St. Louis as pay patients); scarlet fever 61, diphtheria 45, typhoid fever eight, and measles four in Boston; scarlet fever 17, and diphtheria seven in Milwaukee.

In 101 cities and towns of Massachusetts, with an estimated population of 1,336,911 (estimated population of the State 1,955,104), the total death-rate for the week was 26.15 against 16.35 and 15.88 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending May 10th, the death-rate was 21.8. Deaths reported 3666: acute diseases of the respiratory organs (London) 326, whooping-cough 194, measles 176, scarlet fever 66, diarrhœa 47, fever 35, diphtheria 13, small-pox (London 19, Liverpool two, Sunderland one) 22. The death-rates ranged from 14.3 in Brighton to 28.8 in Blackburn; Bristol 18.2; Sheffield 20.5; London 20.6; Birmingham 21.4; Bradford 22.4; Birkenhead 23.5; Leeds 25.0; Nottingham 25.9; Manchester 27.0; Liverpool 27.4. In Edinburgh 23.5; Glasgow 28.7; Dublin 31.8.

For the week ending May 10th, in the Swiss towns, there were 40 deaths from consumption, typhoid fever 38, lung diseases 26, diarrhœal diseases eight, diphtheria and croup five whooping-cough four, scarlet fever one, erysipelas one. The death-rates were, at Geneva 21.4; Zurich 37.4; Basle 20.9; Berne 25.6.

The meteorological record for the week ending May 24th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM MAY 24, 1884, TO MAY 29, 1884.

HALL, WILLIAM R., captain and assistant surgeon. Assigned to duty at Fort Stockton, Texas. Paragraph 1, S. O. 63, headquarters Department of Texas, May 19, 1884.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING MAY 31, 1884.

ANDERSON, F., passed assistant surgeon, ordered to Navy Yard, New York.

BEYER, H. G., passed assistant surgeon, detached from Coast Survey steamer Blake, ordered to Smithsonian Institute for special duty.

RUSH, W. H., passed assistant surgeon, detached from U. S. S. Despatch, and ordered to Coast Survey steamer Blake.

HENEBERGER, L. G., passed assistant surgeon, detached from Navy Yard, New York, ordered to U. S. S. Despatch.

GRIFFITHS, S. H., passed assistant surgeon, ordered to U. S. S. Lancaster on expiration of leave of absence.

JONES, M. D., passed assistant surgeon, detached from Naval Hospital, New York, and resignation accepted, June 15, 1885.

WISE, I. C., surgeon, detached from Academy, and ordered to U. S. S. Constellation.

SUFFOLK DISTRICT MEDICAL SOCIETY. LAST MEETING OF THE SEASON. — *The Section for Clinical Medicine, Pathology, and Hygiene* will hold a special meeting at 19 Boylston Place, on Saturday, June 7th, at 7.45 o'clock. Dr. P. C. Knapp will read a paper on Observations on the Cutaneous and Tendon Reflexes. Dr. F. Minot will report Three Cases of Distended Gall-Bladder.

ROBERT T. EDES, M. D., *Chairman.*
ALBERT N. BLODGETT, M. D., *Secretary.*

NEW HAMPSHIRE MEDICAL SOCIETY. — The ninety-fourth annual meeting will convene in Union Hall, Concord, Tuesday, June 17, 1884, at eleven o'clock, A. M. The following order of proceedings is submitted by the Executive Committee: *Tuesday*, June 17, 1884. (1.) Annual Address by the President, at twelve o'clock. (2.) Essay, An Inquiry into the Causes of Insanity, with especial reference to Prevention and Treatment, Dr. Charles P. Bancroft, Concord. (3.) Oration, Aids in Obstetrics, Dr. I. G. Anthoine, Antrim. (4.) Dissertation, Mothers' Mark Delusion, Dr. M. C. Lathrop, Dover. (5.) Oration, Surgical Cleanliness, Dr. C. R. Walker, Concord. (6.) Report on Surgery, Dr. E. O. Otis, Exeter. (7.) RECEPTION BY THE FACULTY OF THE HARVARD MEDICAL SCHOOL TO THE MEMBERS OF THE MASSACHUSETTS MEDICAL SOCIETY. — Those members of the Massachusetts Medical Society who desire to attend the reception of the Faculty of the Medical School on Tuesday, June 10th, at five P. M., will be able to obtain tickets of the Treasurer at the Institute of Technology on that day.

SUFFOLK DISTRICT MEDICAL SOCIETY, SUMMER PRACTICE. — All members of the Suffolk District Medical Society may send to Dr. Edwin H. Brigham, Medical Library, 19 Boylston Place, the days and hours on which during the months of June, July, August, and September they will be in the city to receive patients, with their addresses. After this information is collected and available a notice to the public will be given through the *Advertiser* and *Transcript*.

DR. E. W. WIGGLESWORTH,
DR. F. I. KNIGHT,
for Executive Committee.

BOSTON MEDICAL LIBRARY ASSOCIATION,
No. 19 BOYLSTON PLACE.

APPOINTMENTS. — The Board of Overseers of Harvard College, at a special meeting held May 28th, voted to concur with the President and Fellows in the following appointments: —

Robert Thaxter Edes, Jackson Professor of Clinical Medicine.

Edward Newton Whittier, M. D., Assistant Professor of Clinical Medicine.

Frank Winthrop Draper, M. D., Assistant Professor of Legal Medicine.

Dudley Allen Sargent, M. D., Assistant Professor of Physical Training and Director of the Hemenway Gymnasium (reappointment).

CORRECTION. — In the report of the meeting of the Boston Society for Medical Improvement, on May 12th, read W. F. Temple.

SEROUS EFFUSIONS IN THE TYMPANUM.[1]

BY J. ORNE GREEN, M. D.

In serous effusions of the tympanum two distinct factors are thought to be the cause of the exudation, inflammation of the tympanic mucous membrane, and closure of the Eustachian tube, the former by producing a thin, serous secretion such as is common from any inflamed mucous surface, the latter by a more complicated process of suction which causes an exosmosis of the serum from the capillary blood-vessels. The conducting mechanism of the tympanum being suspended and necessarily capable of pendulum-vibrations requires that the air on each side of the drum-membrane shall be of equal density, and this equilibrium is retained through the Eustachian tube, which supplies atmospheric air. When the tube becomes closed the air within the cavity undergoes the changes common to air exposed to a vascular membrane, namely, the oxygen is absorbed by the circulating blood, and although a certain quantity of carbonic acid is given off in exchange the whole volume of air is diminished, and the result of this rarefaction is the suction which produces the exosmosis of serum. The further result of this rarefaction is a gradual sinking inwards of the drum-membrane from the over-pressure of the atmosphere, by which the tension of the membrane is abnormally increased, and its capability of vibration greatly impaired. Bezold estimates that the pressure of the atmosphere on the surface of the drum-membrane is six hundred grammes or one and one third pounds avoirdupois, but, of course, only a portion of this is over-pressure, for there is always a certain amount of air left in the tympanum. As a fact, however, it is not unusual to find the drum-membrane pressed inwards so far as actually to lie against the inner tympanic wall.

These two forms of secretion arising from these two distinct causes have been given different names, that due to the inflammation of the mucous membrane being called a serous inflammation, and that due to an exosmosis being called a hydrops ex vacuo. The dividing line between the two is, however, by no means distinct, and in the majority of cases which are seen in practice it seems impossible to determine how far each factor has been concerned in the causation of the effusion. In most cases it seems to me that both are active, sometimes one and sometimes the other predominating.

The ætiology, symptoms, and course of the disease are shown very well in the following cases.[2] When the drum-membrane is translucent the yellowish color of the serum is clearly seen, and if the liquid does not completely fill the cavity the surface of the fluid is clearly seen, like two fine hairs, running from the manubrium, anteriorly and posteriorly, to the periphery, usually in slight curves. If the surface of the liquid changes on bending the head, as it often does when very limpid, or if it varies its position after inflation, the diagnosis is confirmed. Where the drum-membrane is opaque, either from previous disease or from swelling, the history of the case and auscultation during inflation enable one to make a probable diagnosis.

The cure of the disease is effected by reopening of the Eustachian tube and by resorption of the effusion as the inflammation of the mucous membrane subsides, the opening of the tube restoring the equilibrium of the air on the two sides of the drum-membrane, and the resorption of the serum freeing the conducting mechanism, and thus restoring its vibratory power.

The risks are (1) a permanent lengthening of the fibres of the membrana tympani, leaving it in such a flaccid condition that after restoration of the permeability of the tube it is of little use for the transmission of vibrations; (2) permanent retraction of the tensor tympani muscle or adhesions between the drum-membrane and tympanic wall; (3) non-absorption of the secretion and continuance for an indefinite time of the original symptoms. Permanent retraction of the drum-membrane diminishes the size of the tympanum, and even if the existing secretion is absorbed and the parts left with good conducting power a less amount of inflammation is liable, in case of a fresh attack, to produce serious results, than if the cavity was of its full size. Many of the lighter cases undoubtedly recover of themselves and perfectly, the tube opening as the acute naso-pharyngeal inflammation passes off, and the absorption going on rapidly from that moment. But in many the amount of the secretion is so great that even after the opening of the tube and the subsidence of the inflammation nature is unable to effect resorption, at least within the time necessary to save the ear from permanent deformity. Tympanic serous effusions resemble pleuritic effusions in many particulars except that the mechanical causes at work in the tympanum are more distinctly appreciable, and mechanical methods of treatment are more directly applicable.

Politzer's inflation is sufficient in many cases to fulfill both of the indications for treatment, opening the tube temporarily by its current of air, and reducing the swelling by the pressure of the air and by separation of the walls of the tube, and favoring absorption of the secretion by scattering the serum over a larger surface of mucous membrane. Appropriate treatment to the naso-pharynx is sometimes desirable, but often unnecessary. In no class of cases is the effect of inflation so distinctly visible as in those under consideration. Where Politzer's inflation is ineffectual, recourse can be had to the catheter. Under inflation in one of these methods absorption can be effected in from one to three weeks usually, and progress can be seen in the gradual lowering of the line of serum till it finally disappears. When, however, it is evident after several inflations that no progress is being made, paracentesis will give a rapid evacuation with most excellent results, and in exceptional cases its repetition may be necessary.

The cases show very clearly the immediate improvement after inflation when the serum is scattered and the subsequent diminution in hearing as it again collects, the hearing improving more and more, and relapsing less and less till absorption is complete.

The curved lines marking the surface of the serum, and which run from the centre of the drum-membrane to its periphery, forwards and backwards, are probably due to capillary attraction, as the end of the manubrium or centre of the membrane lies nearer the inner wall of the tympanum than the other portions of the membrane do, and capillary attraction of the two sur-

[1] Read before the Boston Society for Medical Improvement, May 26, 1884.

[2] These cases are omitted for lack of space.

faces would hold the liquid at this point at a higher level than where the distance between the surfaces was greater. These curved lines are not infrequently wanting in those cases in which the drum-membrane is completely collapsed against the inner wall, as then the surfaces are equidistant throughout their whole extent, but the curves immediately appear after inflation, which restores to a greater or less degree the natural curvature of the membrane. In exceptional cases the line of the serum is a straight one directly across the membrane. In these cases the serum is so very limpid that capillary attraction of the opposing surfaces of membrane does not act upon it. This fluidity of the serum can generally be demonstrated by changing the position of the patient's head, when it will be found that the surface of the serum has also changed its position, and the patient reports that he could feel the movement in the ear. The more fluid the exudation the more rapidly the absorption takes place.

In regard to the operation of paracentesis tympani, the natural dread of the knife on the part of the patient leads me to try for absorption by inflation before resorting to operative interference, but if, after from two to four inflations, the serum still remains at the same level as at first, or if absorption ceases after progressing for a time, I advise the operation. I evacuate the cavity at one sitting by inflation and by the gentle use of Siegle's speculum, not, however, using the latter long enough to seriously increase the congestion. In the majority of cases the pain from the incision is so slight that it can be easily borne even by little children, partly due, I think, to a partial insensibility of the membrane, produced by the pressure of the fluid. Where, however, the drum-membrane is decidedly inflamed or where the serum has collected in the upper posterior quadrant, requiring an incision in that portion of the membrane, the pain is sometimes acute for a few minutes, but rapidly subsides. Immediately after evacuation the edges of the wound fall in contact, and usually unite in from twenty-four to forty-eight hours, but not so firmly that they cannot be separated by a probe on the next day if further accumulation renders another evacuation necessary.

A few inflations after evacuation are generally sufficient to fully restore the permeability of the Eustachian tube, but till this is accomplished the permanency of the cure cannot be depended upon.

In those cases in which there is little or no swelling of the tissues the relief from the operation is often immediate, the fullness and pressure in the ear, the subjective noises, the dizziness and the deafness ceasing within a few minutes; where there is much swelling of the tissues the relief is more gradual, as time is necessary for the subsidence of the swelling.

SOME OBSERVATIONS ON SOUTHERN CALIFORNIA AND COLORADO.

BY F. H. DAVENPORT, M. D.

I HAVE thought that a few words in regard to Southern California and Colorado, and my impressions of their value as health resorts, might be of interest to your readers. What I shall say will be merely the result of a few months' sojourn, and I recognize the imperfect character of such observations. But they have at least the merit of being disinterested, and as health was the object of my visit, climatic conditions were studied as carefully as the circumstances would permit. As the special aim for which the journey was undertaken, namely, to find a climate in which asthma would be relieved, was not attained, I shall at least hardly fall into the error of too enthusiastic admiration of the climate, a fault which we feel to be only too common with persons who have experienced great benefit in any health resort. Certainly if sunshine, warmth, equable temperature, very little wind, and no cold winds, slight rain-fall, and very little dampness are factors of a good climate we have one here. I personally know of no climate that equals it in these respects, unless it be Upper Egypt during a few months in winter, and that has little else but climate to recommend it. One cannot live there the year round, and it is at present merely the goal of a winter's excursion.

Let me speak a little more in detail as to these several points, and my remarks will have reference more particularly to Santa Barbara, as the greater part of the winter was spent there. The sunshine is a marvel and a delight. During the greater part of the year one can be almost as sure that the sun will shine as that it will rise; and week after week of the most charming Indian summer weather is the rule.

As regards the temperature, there is no cold weather. Hoar frost is occasionally seen, but delicate flowers bloom in the open air the year round. Snow is exceptionally seen for a few hours on the tops of the neighboring mountains, but it never snows in the valleys. The temperature in winter ranges on an average from 40° to 50° Fahrenheit in the morning, 55° F. to 70° F. at noon, and 50° F. to 60° F. in the evening. In summer these figures would be a little higher, but very hot days, with a temperature of 85° F. or over, are exceptional. The equability of the temperature is to my mind the most favorable element of this climate. The diurnal variation is very small, a most important factor in estimating the value of a health resort. The changes through the day are slight, and never sudden. There is no marked chill at nightfall, and if invalids should chance to be caught out at sundown it is not so serious a matter as at many invalid resorts of much wider fame. I am speaking particularly of Santa Barbara. In the neighborhood of Los Angeles, and in general back from the sea-coast among the foot-hills and mountains, there is a cold wave at night which must be trying to delicate persons. Santa Barbara is exceptionally well situated. The sea-coast line runs from northwest to southeast, and the prevailing south to southwest winds come in cool from the broad Pacific. The colder winds of the north and east are shut off by the range of mountains some twenty-five hundred feet high, which half encircle the broad belt of gently rising ground on which Santa Barbara is situated.

There is very little wind, as a rule. For instance, during the months of December and January there was every day a gentle breeze, just enough to ruffle the surface of the water, and only once sufficient to make white-caps. What little wind there is is never chilly, and though an occasional windy and dusty day occurs yet it is so much of an exception that it never need be taken into consideration in sending a patient thither.

I found, before going to California, that there was a great deal of misconception about the so-called "rainy

season." The expression naturally calls up to mind a series of months when rain falls pretty constantly, interfering with out-of-door exercise, causing mud and dampness, and a generally uncomfortable state of affairs. Such is by no means the case. Rain may occur from November to May, but there is usually very little except in January, February, and March, and even then an occasional rainy day, or a shower in the night, followed by bright sunshine, is the rule. As the whole rain-fall, which averages about fifteen inches, is distributed through five or six months, the amount of unpleasant weather is very small, not enough to interfere with the comfort of the most delicate patient. There is an occasional wet season when the greater part of the rain-fall occurs in one or two months, and rivers overflow their banks, travel is interrupted, and the roads become almost impassable from mud. Such has been the winter just passed, there having been the greatest rain-fall for over twenty years. In February a great deal of rain fell, more than eighteen inches in the course of three weeks; but with the exception of annoyance from delayed mails and interrupted communication it was not serious. Invalids did not seem to suffer from it, and for two reasons: first, it was not a cold rain; and, second, when the sun shone out again the roads dried rapidly in the town and its immediate neighborhood, and wonted carriage or horseback exercise could be resumed.

Two other sources of dampness are dew and fog. There is a very moderate dew-fall, and what there is seems to be precipitated in the early morning, and at sundown and in the evening there is no marked dampness. What falls in the night is so quickly dried by the sun as to cause no inconvenience whatever. Fogs occasionally occur, but are not disagreeable. They are warm and soothing, as there is a decided absence of that raw and chilly element which makes them so undesirable on our coast.

We have here a climate which would seem to possess very few serious disadvantages, and where we should expect patients with affections which need a mild, equable, and moderately dry climate to improve. Of such affections lung troubles form by far the largest contingent, and in the majority of cases they justify the reputation of the climate. More time than has yet been devoted to the subject, larger experience, and more accurate observation are needed before we can define with precision exactly what forms of pulmonary disease are most benefited by this climate. With regard to phthisis, I should select Southern California in preference to other health resorts for cases which were not predisposed to hæmorrhage, where the consolidated portion of lung tissue showed a tendency to break down, and even in cases of cavity formation, especially if there were very free secretion. The strength of the patient is an important factor in deciding. Where the strength has become markedly reduced, and there is so much prostration that exercise is impossible, I should choose California rather than Colorado, for instance. The climate is so mild as to make an out-of-door life possible for the most delicate invalid, and only as the patient gained strength would a greater elevation and a more stimulating air be advisable.

Chronic bronchitis, especially of the dry form, where there is some emphysema, and the heart has difficulty in doing its work, is one of the diseases most likely to be helped. So, too, chronic throat affections, pharyngitis, and laryngitis, and catarrh in its various aspects. Many asthmatics find that they are better in Southern California, but generally experience more relief at points of greater elevation than Santa Barbara.

While California will always be a favorite health resort for consumptives, and increasingly so as it becomes better known, and travel becomes easier, yet I am sure that nervous debility will claim it more and more for itself. I know of no climate better fitted for the broken-down man of business, or the nervous invalid, to whom the slightest household care is a burden. There is something so seductive in the air and sunshine and warmth that one is perfectly contented to do nothing but breathe and enjoy nature. The universal testimony of those who have lived there a series of years is that ambition is forgotten, energy is lost, and one gets into such a placidly tranquil state of mind (demoralized we should call it) that nothing worries or disturbs, and life is not a problem to be solved, but a *dolce far niente* existence to be enjoyed.

Neuralgic affections are especially helped in this climate, while rheumatism would be rather a contra-indication.

The choice of a climate is in most cases a matter of intelligent experimentation, and experience shows that cases which for a time are benefited on the sea-coast yet now and then need a change inland. There is within easy access of Santa Barbara a health resort which combines most of the advantages of that place with greater elevation and consequently more bracing air. This is the Ojai Valley, which has a deservedly growing reputation. It is fifteen hundred to two thousand feet above the sea-level, cut off from winds, and possessing a very pure air.

Santa Barbara and the Ojai Valley together possess nearly all the requisites of a thoroughly good climate.

By all means advise patients to consult some local practitioner. There are many minor points which only such knowledge as comes from residence in a place will suggest, which, though small, are by no means unimportant.

I propose to say but little of Santa Barbara in other respects. A few practical hints, however, as to accommodations, cost of living, and other incidental expenses may not be out of place. One has a choice of three modes of living, — in a hotel, in a boarding-house, or keeping house. Hotel life involves the least care, but is the most expensive. Santa Barbara has two good hotels, one of which, the Arlington, is the best in Southern California. By the month the expense is from two dollars and a half to three dollars a day, and the accommodations and table are thoroughly good. I should consider the freedom from the cares of housekeeping, the pleasant social element which may be cultivated or not as the person chooses, and the independence which one could not have in a small boarding-house, as elements particularly favorable for most invalids.

There are several very good boarding-houses in Santa Barbara, where the expenses are about two thirds what they would be in the hotel. They are very small, however, being merely dwelling-houses, with at most three or four rooms for guests, and unless a party of friends could take the whole house there might be a great deal of annoyance on the part of invalids from noise, and on the part of well people from the constant sight of some poor invalid, or the

hearing an incessant cough. The table at several of the boarding-houses is said to be very good.

Housekeeping, with the one exception of servants, is said to be very easy. Cottages to rent for the season are very numerous, and many of them exceedingly attractive. Good furnished cottages can be had for from thirty dollars to sixty dollars a month, unfurnished for from twenty dollars to thirty dollars. An occasional open fire at morning and night is all that is needed in the way of heating. Provisions would average about the same as in the East, meats and vegetables being cheaper, and some groceries dearer. Chinese servants are almost exclusively employed, and their wages range higher than servants' wages here.

Good saddle-horses can be bought for from fifty dollars to one hundred dollars. They can be hired by the month for twenty-five dollars, or a horse and buggy for forty dollars, and for a short stay that is decidedly the best arrangement.

For any one who contemplated staying more than six months I should by all means recommend hiring a house as, on the whole, the most satisfactory way to live. For persons who are well enough to go out without regard to the weather a modification of housekeeping may be tried by renting a house near one of the hotels or boarding-houses, and taking meals at the latter. In that way more quiet is secured than in the hotel, and the bugbear of servants is avoided.

There are good educational advantages in Santa Barbara, very agreeable society, a pleasant club, and churches of all denominations. There are a great many more physicians than can make a living, most of them obliged to live there on account of their health. Zymotic diseases are very rare, and the severe diarrhœal diseases of children are almost unknown. Children do remarkably well, as they rarely take cold, and can be out of doors at play almost every day of the year. Taking it all in all, while there are many disadvantages in an enforced residence in Southern California there are a great many compensations.

I spent a few weeks in Colorado Springs on my return, and was interested to compare the two climates, so radically different, and yet both advancing such strong claims as health resorts for consumptives. In both places I found profound distrust of the other, and in Colorado Springs it was the opinion that it was almost sure death for a consumptive to go from there to California. Several cases in point were cited, and I myself should consider it much the safer course to go from California to Colorado than the reverse. From the stimulating air of Colorado the let-down is too sudden.

Colorado does not impress a stranger as a remarkably good climate. It is very changeable, windy, and at times intensely cold or hot, and has a markedly stimulating effect on the whole nervous system. But facts speak louder than theories, and the facts are that consumptives, many of them with but fractions of lungs in working order, improve and live a comfortable life. The explanation seems to me to be the dryness and pureness of the air. Certainly if with so changeable a climate there were dampness, such good results as we find would be impossible. One result of the changeability of the climate is that part of almost every day is warm and pleasant enough for invalids to be out. The sun's rays are very powerful, and even with the thermometer at zero it is warm in the sun.

One would suppose that the effect of an altitude of over five thousand feet on the circulation, quickening and stimulating it, would be to favor hæmoptysis, but such is not the case. The hæmorrhagic cases do well, as a rule, and a primary hæmorrhage occurring in Colorado is an exception. The cases where there is consolidation without cavity formation do best, and in many instances areas of dullness diminish and clear up with astonishing rapidity. Cases farther advanced, where there is already breaking down of lung tissue, do not do as well, and when a change of climate seems advisable in such cases I should choose California rather than Colorado.

The claims of both these great sections should not be ignored. It is absurd to send all patients to one or the other. There are cases which will do better in Southern California than anywhere else, just as there are cases which need the dryness of air and elevation of Colorado. To determine which place will suit the given case requires most careful study. The temperament and habits of the patient, extent and rate of progress of the disease, ability or not to take exercise, state of the mucous membranes of the air-passages, and a great many other points, should be carefully considered. Only as that is done can the best results be expected from a change of climate.

I heard a great deal said about the climate of New Mexico and Arizona, but only passed through these territories en route for California, so cannot speak from personal experience of their value. I only know that the air seemed to us to have an exceptionally pure and bracing quality, different from any other part of our journey. It seemed to allay all irritation of the mucous membranes, and it was a delight to breathe it. I think these territories have a great future before them as health resorts. There is a table-land which stretches on the eastern side of the Rocky Mountains even down through Mexico, at a varying altitude of from four thousand to seven thousand feet, which has virtually the same climatic conditions, and I feel sure that places will be found which will unite the advantages of Colorado health resorts with a less rigorous winter climate.

RECENT PROGRESS IN OPHTHALMOLOGY.

BY O. F. WADSWORTH, M. D.

THE JEQUIRITY QUESTION.

THE enthusiastic announcement by De Wecker, nearly two years ago, of the merits of infusion of jequirity in the treatment of trachoma has been followed by the publication of numerous articles on the subject. Our readers will remember a paper in this journal by Dr. Standish, one of the earliest on the subject published in this country, giving a detailed account of the results of this treatment in a series of cases. The success attained was a very gratifying one in view of the generally obstinate nature of the affection and its great tendency to relapses. But it appeared there that the claim made by De Wecker of the innocuousness of the remedy as to ulceration of the cornea was not altogether justified. Still stronger instances of serious implication of the cornea from the use of the drug have been presented by others. The general verdict, however, has been that the new remedy is of much value when employed with caution and in properly selected cases. Precisely what is the range of disease in which jequirity may be safely used cannot yet be

regarded as settled. It would seem at present that its application should be much more narrowly restricted than De Wecker proposed in his early communications, and that unless there be a pannus of the cornea it is more likely to be injurious than beneficial.

In a recent paper De Wecker [1] gives the conclusions drawn from a very extended experience of the method. He thinks it important that the infusion should be used when fresh, as an unpleasant odor is developed after a few days, and when old it is not so reliable in its action. A three per cent. infusion is generally employed; a five per cent. in cases of dry degenerated conjunctiva only. The infusion is applied but once, being thoroughly rubbed on the conjunctiva of the inverted lids and fornix by means of a sponge dipped in it, but with avoidance of the cornea. In most cases a single such application is sufficient to produce a violent ophthalmia, and if the trachoma is not cured a second and a third application is made at an interval of at least two or three weeks. The dangers of jequirity ophthalmia are two: the employment of strong infusions in too rapid succession, and application to a conjunctiva already discharging. With pannus of the cornea this writer asserts that an intense inflammation excited by a single application brings no danger to the cornea, but an undue increase of a beginning ophthalmia by farther use of the drug or its continuance when there is already a purulent discharge does endanger the cornea, for there is then produced not the specific jequirity ophthalmia, but an increase of the preëxisting purulent conjunctivitis. The remedy should not, therefore, be used when there are suspicions of chronic purulent ophthalmia, but only in cases in which the granulations are dry. If the cornea is intact treatment with jequirity is rather harmful than beneficial, for such cases greatly resemble chronic purulent conjunctivitis with marked papillary hypertrophy. The few cases which have been observed in which the inflammation extended by inoculation to the other eye are to be explained by the production of purulent ophthalmia in a conjunctiva unsuitable for the treatment, true jequirity ophthalmia not being so transmissible.

The efficiency of jequirity in simple and ulcerous pannus De Wecker considers established without doubt. He also claims that, according to his observations, its use is attended with no danger in parenchymatous keratitis and chronic infiltration of the cornea, which clear up with more or less certainty and to a greater extent than has ever been attained with syndectomy. He quotes one of his assistants, who had experimented on three hundred patients, that torpid central corneal ulcers, especially those due to cicatricial keratitis and torpid scrofulous pannus, with or without ulcers, may successfully be subjected to this treatment. In these diseases, however, the swelling of the conjunctiva and the amount of purulent secretion must be considered in determining whether jequirity should be used.

The experience of others with jequirity has not always been so rose-colored. Several oculists gave the results of their employment of jequirity in the journal in which the above paper appeared. From consideration of these and other publications it appears that the susceptibility of individuals to the action of the remedy is by no means uniform. The pain induced by the application is often very great; sometimes severe rigor, fever, and prostration have been caused. There have been glandular enlargements in some cases. Not only ulceration but perforation of the cornea has occurred in several instances, even when there was pannus of the upper half, at least, of the cornea, and a weaker solution than that last advised by De Wecker was used, though the treatment was not always confined to a single application. Knapp [2] reports a case of ordinary trachomatous pannus, no discharge, no corneal ulcers, in which a single brushing of a fresh three per cent. solution, macerated three hours, over the everted upper lid was followed by a most intense reaction; membranes marked, and when, three days later, they were cast off, a most violent pyorrhœa followed, which, in two days, affected the other (not inoculated) eye; extensive central perforating ulcers in both corneæ. Severe dacryocystitis has also been observed.

In acute trachoma with clear cornea jequirity has often aggravated the inflammation, sometimes has cured the granulations with the formation of dense cicatrices. In chronic trachoma with vascular and secreting conjunctiva the condition is usually made worse. In chronic trachoma with more or less cicatrized conjunctiva, without secretion and with pannus, the result from jequirity is often brilliant, at least so far as the pannus is concerned, and more rapid than by any other method of treatment. But even here, although the pannus clear up, granulations of the lids, if present, often persist, and while relapse of pannus seems to be very much less frequent than after other methods it is not unknown. Danger to the cornea, other things being equal, is inversely as the amount of pannus.

The widespread acceptation that the germ theory of disease has acquired at the present day made it natural that its aid should be invoked to explain the inflammation excited by jequirity. De Wecker early suggested that a vegetable ferment was the active agent concerned. Sattler [3] undertook an extended series of experiments on man and rabbits to determine the nature of this agent. He described a period of incubation of some three hours between the application of the infusion to the conjunctiva and the first appearance of subjective and objective symptoms, and considered the whole course of the inflammation to bear a strong resemblance to that of an infectious disease.

Attempts were made to discover some chemical substance in the infusion which would produce the inflammation, without success. There was found invariably, however, in the fluid, sometimes immediately after filtration, usually only some hours later, a definite variety of bacillus, which rapidly increased in numbers and soon began to collect at the surface and to produce spores. The film thus formed sank after some weeks, and the fluid gradually became clear. It was in accord with these changes that the activity of the infusion was found to be greater at first, but after a time to be wholly lost. The same bacillus was found in small quantity in the purulent secretion of the conjunctiva and in the membranous exudation, and the scanty presence of the bacillus here was regarded as explaining the circumstance that the secretion of jequirity ophthalmia, applied even repeatedly to the healthy conjunctiva, excited but a mild degree of conjunctivitis. The bacillus was also found in the infiltrated conjunctival and subconjunctival tissue.

Endeavors were made to obtain an infusion free

[1] Archives of Ophthalmology, xiii., 1.

[2] Loc. cit.

[3] Klinische Monatsblätter für Augenheilk., June, 1883.

from bacilli. Boiling for half an hour to an hour invariably made the infusion wholly ineffective. This procedure, however, also precipitated the albumen naturally present in considerable amount, and when the fluid was separated from the precipitate by filtration and exposed to the air only a feeble generation of the bacillus took place. Addition of bichloride of mercury to the jequirity infusion in the proportion of one to 10,000 stopped the development of bacilli; but the infusion still excited a severe ophthalmia. Here the discovery of spores floating in the fluid and capable of development when transferred to a suitable material was regarded as accounting for the ophthalmia.

Stronger solutions of sublimate destroyed the germs. Thymol (one to 2000) did not prevent the development of spores or of inflammation.

By careful observation of precautions against the admission of germs Sattler succeeded in preserving for weeks, in a flask stopped with cotton wool, an infusion wholly free from germs. Nevertheless, when this infusion was carefully dropped upon the conjunctiva it excited a marked ophthalmia. This result Sattler readily explained by the supposition that it must have been difficult to prevent germs free in the air from reaching the conjunctiva during and after the application.

Finally, pure cultures of the bacillus were made. The cultivated bacillus placed in the conjunctival sac caused a conjunctivitis. After a single application the conjunctivitis was mild, and in twenty-four hours only slight traces of it remained. A number of applications at intervals of one or two hours excited the characteristic diphtheritic exudation in the fornix conjunctivæ, and the inflammation continued several days. Sattler considered it proven that the ophthalmia was caused by the bacillus in question. This bacillus, however, was not originally in the jequirity pea, but one whose germs were very generally present in the air. Under ordinary circumstances innocuous, when transplanted to a suitable soil (jequirity infusion) it developed a pronounced malignancy. He admitted that a bacillus of similar appearance and like behavior on cultivation was to be found in infusion of ordinary peas, but claimed that the conjunctivitis caused by pea infusion containing the bacillus was very mild.

Two years earlier Sattler[1] had described a micrococcus in the granules of trachoma, which he believed to be the cause of the disease. Now, in view of the curative action of jequirity in trachoma, he considered that, just as the new bacillus in jequirity infusion prevents the development of all other germs that may be present there, so in the trachomatous conjunctiva it modifies the condition of the tissues in such a manner as to deprive the micrococcus which has produced the trachoma of its means of existence.

Sattler's position did not remain long uncontroverted. Hippel[2] came to very different conclusions. He also experimented on man and rabbits. He denies the analogy with infections, asserting that there is no period of incubation, and that if the disease were infectious it should be easily capable of propagation by the secretions. His attempts to prevent the development of the bacillus by solutions of sublimate, even as strong as one to 5000, were unsuccessful. Yet he points out that he was able to produce in the rabbit by solution of sublimate alone (one to 6000) a violent conjunctivitis, with diphtheritic infiltration, necrosis of conjunctiva, and destruction of the eye. Regarding the possibility that sublimate might, by chemical action, not by its antiseptic properties, prevent the effect of jequirity, he used one half to two per cent. carbolic acid, one third to one sixth per cent. salicylic acid, and four per cent. boracic acid solutions. With all he was able to preserve the infusions for months free from bacilli, and although there were particles in the fluids which might have passed for spores, careful attempts at cultivation of these wholly failed. Yet the infusions, even when three or four months old, excited the same violent ophthalmia as did fresh watery preparations swarming with bacilli. Hippel found in infusions both of hay and peas a bacillus strongly resembling that of jequirity, and was able by repeated applications of these to produce in rabbits severe conjunctivitis, with adherent gray exudation in the fold of transmission, and secondary affection of the cornea. Farther, an oily substance with strong odor of jequirity was prepared by Gähtgens by treatment with ether. This, used in the form of a neutral emulsion, caused in two rabbits a thoroughly characteristic ophthalmia, with the single difference that the inflammation developed more slowly. The experiments were too few, however, to determine if this really contained the active principle of the drug.

Still more recently Neisser,[3] in Breslau, Klein,[4] in London, and Salomonsen,[5] in Copenhagen, have published the results of experiments undertaken to determine the influence of Sattler's bacillus in causing the jequirity ophthalmia. Neisser and Salomonsen agree that there is a so-called period of incubation, but without giving it the significance Sattler attached to it. All confirm the observation of Sattler that a sterile infusion possesses full virulency, and concur in the statement that the bacillus is not the active agent.

Neisser and Salomonsen even assert that, instead of the bacillus causing the inflammation, it is this which after a time destroys the potency of the jequirity, while, on the other hand, the activity of the infusion is preserved so long as it is kept free from germs. All were unable to find the bacillus in the secretions, or in cultures made by inoculating suitable soils with the pus and membranes. Boiling, or, according to Neisser, even long standing at a temperature of 38° C. to 39° C., destroyed the efficacy of the drug. Finally, Klein, having sterilized infusions by boiling, inoculated them with bacilli and spores from another preparation, and when after twenty-four hours they were swarming with bacilli found their application to the conjunctiva entirely ineffective.

— The following elephantine dose was recently administered by the attendant veterinary to one of Barnum's secular elephants, "Allah," which was attacked with enteritis while in Cincinnati: Lard, eight pounds; linseed oil, one gallon; tincture of opium, one pint; spirits of nitrous ether, one pint; syrup, one quart. The lard and oil were first mixed, then the other ingredients added. The trunk was raised above the head and the mixture poured down the throat through a large metal tube. His elephancy recovered.

Reports of Societies.

THE ANNUAL MEETING OF THE PENNSYLVANIA STATE MEDICAL SOCIETY, MAY 14, 15, AND 16, 1884.[1]

THIRD DAY'S PROCEEDINGS.

PROFESSOR LEIDY, President of the Anatomical Board of the State (appointed under the law recently adopted to protect dissection by the distribution of cadavers from various public institutions throughout the State to the colleges), addressed the Society, and requested the coöperation of the medical profession of Pennsylvania in seeing the law faithfully and fairly executed.

DR. N. S. LITTLE read the address in Ophthalmology, in which he discussed the value of pupillary symptoms in general disease, based upon the records of 1000 cases.

DR. EDWARD JACKSON, of Chester County, in a brief communication called attention to the danger of Poisoning by Mydriatics, and referred to a number of fatal cases.

A FORM OF EPITHELIAL MYCOSIS FROM A CLINICAL STAND-POINT

was considered in a paper by DR. ALBERT G. HEYL, in which he discussed the relations of micro-organisms to certain diseased states, and directed especial attention to forms of bacterial infection observed in the eye, not always limited to the conjunctival epithelium, but seen in other localities. This affection is almost always fatal.

AN ELECTRIC LARYNGOSCOPE

was shown by DR. CARL SEILER, which consisted in a small arc-lamp fixed in front of the mirror on the forehead of the observer. It was operated by a storage battery.

DR. J. SOLIS COHEN exhibited Trouvé's polyscope for examining the larynx, and for rhinoscopy.

In a communication entitled Does Chronic Discharge from the Ear make Life Insurance Hazardous? DR. CHARLES L. TURNBULL answered the query in the affirmative, after considering the reports of a number of cases.

DR. PETER D. KEYSER in a conclusion of the paper read at a former meeting, on Some Ophthalmological Observations during Ten Years' Service in Wills' Eye Hospital, gave a number of clinical histories of cases of affections of the choroid, retina, optic nerve, recti muscles, sclerotis, vitreous, etc., with some anomalies of refraction.

THE ADDRESS IN SURGERY

was delivered by DR. JOHN B. ROBERTS, of Philadelphia, who exposed some "surgical delusions" with regard to the safety of chloroform anæsthesia; the value of styptics, dangers of trephining the skull, necessary fatality of heart wounds, lateral symmetry of normal limbs in the same individual, and one or two other points of interest.

DR. E. T. BRUEN read a paper upon the

OPERATIVE TREATMENT OF PURULENT PLEURAL EFFUSIONS,

written in conjunction with Dr. J. Wm. White, in which he detailed the indications for the operation; gave a résumé of thirteen cases in which it had been performed, with the report of an original case in which a section of three ribs was removed with good results.

DR. C. B. NANCREDE, in a paper on

THE BICHLORIDE OF MERCURY AS A SURGICAL DRESSING,

spoke enthusiastically in its praise, and reported cases of amputation of breast and other major operations which healed without a drop of pus.

PUBLICATION OF PAPERS AND ABSTRACTS.

Upon reassembling in the afternoon the report of the Committee upon Publication of papers and abstracts was presented as follows:—

"All the papers read or appointed to be read before this Society become thereby the exclusive property of the Society, and the author has no right to publish or cause to be published the paper or any part of the same without the consent of this Society. The Committee on Publication shall not be at liberty to publish any paper that has been published in violation of the above requirements.

"*Resolved*, That the Medical Society of the State of Pennsylvania look with great disfavor upon the making use of this organization as an advertising medium, and hold such practice as contemptible as a flagrant violation of the spirit of the Code of Medical Ethics."

This was adopted with the amendment that the Society reserved the right to furnish abstracts or to permit them to be furnished for publication.

DR. DE FORREST WILLARD read an excellent paper upon

NON-NECESSITY OF TARSOTOMY IN TALIPES OF CHILDREN,

and presented cases showing the value of manipulation and stretching with proper apparatus. He exhibited a form of apparatus in which a shoe on the affected foot was attached to a belt around the pelvis by a vertical, lateral steel rod, jointed opposite the knee and thigh, in connection with which was a long spiral spring, which by a constant action everted the toes. Cases were shown and photographs passed around to prove that tarsotomy is not needed in children even when the deformity is great.

DR. A. SYDNEY ROBERTS exhibited several cases illustrating the application of a new form of splint to the treatment of Chronic Articular Osteitis of the Knee-Joint, and DR. W. S. JANNEY exhibited a case of deflection of the trachea, in which the presence of a large tumor of the neck had required the performance of tracheotomy.

REPORTS, RESOLVES, AND ANNOUNCEMENTS.

A favorable report on the plan submitted during the first day to found a society to organize a State Board of Health, and to help educate the community in medical matters and the principles of health was adopted without debate.

Resolutions paying tributes to the memory of the late Professor Gross, and proposing the erection of a monument to him in Fairmount Park, were unanimously approved.

The time for the next meeting, at Scranton, was changed from May 2, 1885, to the last Wednesday in May, on account of the proximity of the former date

[1] Continued from page 535.

to the time of the meeting of the American Medical Association in New Orleans.

The announcements for the regular addresses in next year's session were made as follows: In surgery, Dr. E. A. Wood, of Pittsburg; in obstetrics, Dr. C. A. Rahter, of Harrisburg; in hygiene, Dr. J. G. Richardson, of Philadelphia; in mental diseases, Dr. S. S. Schultz, of Danville; in otology, Dr. C. S. Turnbull, of Philadelphia.

Just previous to the adjournment *sine die* the new President, DR. E. J. ALLEN, was introduced by the ex-president, who made some valedictory remarks, and welcomed his successor, to which Dr. Allen responded in a few words, thanking the Society for the honor conferred. The Association then adjourned.

PROCEEDINGS OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M. D., SECRETARY.

MAY 26, 1884. The President, DR. CHARLES D. HOMANS, in the chair.

SPECIMEN ILLUSTRATING PROGRESSIVE MOVEMENT OF DERMOID LINING OF EXTERNAL AUDITORY CANAL.

DR. F. H. HOOPER showed a specimen which had been removed from the ear, and which came away sticking to a ceruminal plug. The specimen represented the dermoid coat of the membrana tympani and of a portion of the external auditory canal. When first syringed out it was rolled up into a compact mass, but on being placed in water it unravelled to its present length, which is four inches and a half. Its width is half an inch. The specimen illustrated very well the progressive movement from within outward of the dermoid lining of the external auditory canal and of the outer coat of the membrana tympani. This movement has long been recognized, and even the direction with which it takes place has been demonstrated by Dr. C. J. Blake's ingenious observations on the subject. In this instance the epidermis in its outward movement, meeting with the resisting plug of cerumen, gradually folded up on itself (like the sides of an accordion when the instrument is closed); which explains how a mass of this length could be accommodated in the small portion of the meatus between the ceruminal plug and the drum-membrane.

DR. J. ORNE GREEN said the specimen shown was an unusually large and perfect one. In regard to the mode of formation of these collections it would be interesting to know whether the roll lay across or lengthwise of the meatus, and he was not aware that this fact had been as yet noted; if the explanation given was the correct one, we should expect it to lie across. For himself he was unable to accept the undoubted outward growth of the dermoid layer of the drum-membrane as explanatory of all or even of the majority of these epidermal collections in the meatus; for such were often found on a circumscribed portion of the walls of the passage only, even in the extreme outer portions, all other parts of the walls and of the drum-membrane being healthy. He was rather inclined to refer them to what has been called "desquamative inflammation," which leads to large collections of epidermis, sometimes in the tympanum proper, sometimes in the mastoid cells, and not infrequently in other parts of the body, as the vagina. It might be that further investigation would show that collections like the one under discussion, consisting of a distinct roll of epidermis, were influenced to take the form of a roll by the dermoid movement, but even in these cases it seemed to him we must assume a pathological process to account for the enormous epithelial development.

DR. HOOPER, in answer to a question by Dr. Minot, said that the patient complained of deafness. Both ears were full of cerumen, and this compact mass was syringed out. The drum was much injected, yet there had been no history of inflammation. Hearing is now perfect.

LINKS OF ARTICULATED CATHETER REMOVED FROM THE BLADDER.

DR. J. COLLINS WARREN showed several links of an articulated metallic catheter, which had broken off in the bladder when passed by the patient, an accident which has happened several times. They had been retained some six months, and he used the lithotrite, expecting to break up incrustations and separate by evacuation. At the first introduction several pieces of catheter were caught and brought away. Others were washed out, and on using the lithotrite again it became locked, and would not easily open. By means of incising the meatus, a link which formed a barb with the jaws of the instrument was withdrawn. There proved to be little or no incrustation.

DR. R. H. FITZ read a paper on

THE IMPORTANCE OF PERSISTENT OMPHALO-MESENTERIC REMAINS AS A CAUSE OF INTESTINAL OBSTRUCTION.

The report of the discussion on this paper is delayed by request of Dr. Fitz.

DR. J. ORNE GREEN read a paper on

SEROUS EFFUSIONS IN THE TYMPANUM.[1]

Dr. Green said in answer to Dr. C. J. Blake that he thought paratencesis was indicated in a case of effusion without congestion, provided it were not absorbed by inflation.

DR. C. J. BLAKE said that among the causes for hydrops tympani were closure of the Eustachian tube, which commonly includes some congestion; the presence of nasal polypi, when the condition can be removed by the removal of the polypus; and reflexes affecting the vaso-motor nerves of the part. He mentioned a case of exposure to cold during a drive, which was followed in two hours by great pain, with swelling and bulging of the upper part of the tympanum, which was transparent with effusion, although there was no liquid in the middle ear. The condition, if not relieved, would grow worse. Inflation was impossible, and paracentesis caused the collapse of the bulged membrane with a sharp hiss of escaping air. An hour later there was a free serous discharge. He asked the reader if he is ever obliged in these cases to use the Eustachian bougie.

DR. GREEN said that he thinks either Politzer's inflation or the catheter can commonly be used in this condition. He would not, however, hesitate to use the bougie if they failed, and he does use it in other forms.

[1] See page 553 of this number of the JOURNAL.

Dr. S. W. Langmaid expressed his opinion that most people are unable to have the nostrils long occluded without risk of effusion in the ear, and that the risk is increased if there is at the same time a pharyngeal stenosis, from whatever cause.

Dr. Green said that he had not intended to go into anything but the common forms, and he wished to dwell particularly on the diagnosis and treatment.

Dr. G. K. Sabine asked if there is any value in the common practice of inflating the ear by blowing against the fingers.

Dr. Green thought it would only be possible in simple cases. It is partial, and it may do harm by causing congestion of the whole head, while from the frequency with which the patient is tempted to use it there is danger of stretching the drum.

PERCEPTION OF MUSICAL NOTES IN ANIMALS.

Dr. C. J. Blake showed a whistle invented by Francis Dalton in which the pitch is regulated by a screw. By the use of this it is found that small dogs appreciate a higher pitch than large ones. Experiments are now in process on cats.

ESSEX NORTH DISTRICT MEDICAL SOCIETY.

H. F. Adams, M. D., Corresponding Secretary, Reporter.

The regular annual meeting of the Essex North District Medical Society was held at the Eagle House, Haverhill, March 7, 1884, Dr. J. A. Douglass, of Amesbury, President, in the chair.

The annual address was by Dr. E. P. Hurd, of Newburyport, Vice-President of the Society; subject

CEREBRAL LOCALIZATIONS.

The following is a synopsis: The essayist divided his topic into four heads: First, the general physiology of the cerebrum; second, regional physiology; third, psychical evolution and cortical centres; fourth, the explanation.

Under the first head, he said, there was general agreement that the hemispheres were the seat of the intellectual operations and of volition, as proved by mutilations in animals (removal of parts or the whole of the cerebrum) and the effects of disease in man (atrophy, inflammation, œdema, etc.). Grave lesions of the encephalon, whether morbid or experimental, are always attended with enfeeblement or disappearance of the psychical faculties, and it is a fact, too, that motility also suffers in a marked degree.

When we come to the matter of regional physiology, we find ourselves in the midst of problems that still await complete solution. The first and capital fact in cerebral localizations was the discovery by Broca in 1861 of the speech centre in the posterior part of the third frontal convolution of the left hemisphere.[1] Thousands of observations have confirmed Broca's thesis, and lesions of Broca's convolution extending into the pre-frontal lobes are found to be attended not only with aphasia but with amnesia, — loss of the memory of ideas, as well as of words and verbal expression. Other considerations, such as the effect of destruction of these inexcitable (pre-frontal) lobes, go to show that their main function is psychical. Hughlings Jackson thinks that they are *par excellence* the motor substrata, but if any motor influence emanates from them (and anatomically these lobes certainly seem to be connected through the corona radiata with the motor portion of the cerebro-spinal axis), such motor influence must be of an inhibitory character, that is, restraining rather than exciting. We have certainly instances of motor neurility which is inhibitory in the cardiac branches of the par vagum, the depressor nerve of Cyon, etc. As to the functions of the parietal lobes, Ferrier's carefully conducted experiments seem to prove that they are motor rather than psychical; this is especially true of certain areas of gray matter bounding the fissure of Rolando, electrical stimulation of which produces definite motor results, destruction of these areas being followed by local paralyses, as of limbs. The phenomenon of descending degeneration of the medullary strands between Ferrier's cortical centres and the basal ganglia, in the case of lesions of the so-called motor regions, and the coincidence of this degeneration with similar degradation of the motor columns of the spinal cord, as noted by Charcot and Flechsig, seems to point to direct anatomical connection between the anterior and crossed pyramidal columns of the spinal cord and those cortical regions. Franck and Pitres have obtained similar results by section of the fibres proceeding from the gray matter bounding the fissure of Rolando, secondary degenerations occurring precisely similar to those which are seen in motor nerves after their separation from their trophic centres in the spinal cord, and they reason from this that "the medullary fibres between the cortical centres and the lower motor nuclei bear the same relation to the nerve cells of the cortex as the spinal motor nerves to the multipolar cells of the anterior cornua."

Experimenters working in the same direction with Ferrier (Carville and Duret, Luciani and Tambourini,

[1] The whole subject of aphasia is a complex one, nor have we yet the data for its complete exposition from the stand-point of definite anatomical bases.

Broca's convolution is regarded as the seat of language expression, that is, the centre from which volitional incitations to movements of articulation pass downwards. At the same time there are several well-attested cases on record which go to show that lesions in the neighborhood of (that is, posteriorly and below) Broca's centre are attended with aphasia, often with verbal surdity and blindness. I call particular attention to the Contribution to the Study of Aphasia by Dr. Balzer in the Gazette Medicale de Paris, March 1 and 15, 1884. In one of Dr. Balzer's cases there was marked motor aphasia and agraphia with verbal blindness and deafness and general intellectual obtusion. The autopsy disclosed (on the left side) softening of the first temporo-sphenoidal convolution, the lower portion of the inferior parietal lobule, and the *pli courbe;* that is, the centres of sight and hearing were involved. Here, although Broca's speech centre was not directly affected, it is easy to understand that an extensive lesion in the vicinity might have had a considerable inhibiting influence on that centre, especially when it is taken into consideration that an important branch of the Sylvian artery was found calcified. Moreover, the auditory and visual centres on the left side were destroyed. The language function is so associated with ideation generally, and normal ideation is so dependent on integrity of the perceptive centres, that serious lesion of the latter must impair (if it does not render utterly impossible) all reminiscential reproduction. In other words, verbal expression must be lacking when the memory of words is gone.

Balzer's second case was one of pathological "muteness." The left temporo-sphenoidal lobe was "a mass of pus." There was considerable congestion of the inferior portions of the left frontal lobe, and slight adhesions of the membranes. The observation is imperfectly reported, and on the whole is hardly to be regarded as evidence against Broca's doctrine

His third observation is carefully reported. It is a case of tuberculous meningitis on the left side, and the general symptoms, coupled with the post-mortem revelations, remarkably sustain the doctrines of localization as propounded by Ferrier. There was right hemiplegia and lesion on both sides of the fissure of Rolando, motor aphasia, verbal blindness and deafness, agraphia with meningo-encephalitis of Broca's convolution, the temporo-sphenoidal lobe, and the angular gyrus. Tuberculous meningitis seldom lends itself to the elucidation of cerebral localizations. In this instance the data were sufficient to sanction quite positive conclusions.

notably Yeo) have added confirmation to Ferrier's views, and hundreds of clinical and post-mortem observations have demonstrated the concomitance of general or limited paralyses with lesions more or less circumscribed of those portions of the parietal lobes now known as Ferrier's centres.

Among the important contributions which have appeared in American medical journals, throwing light on certain aspects of the subject, were signaled the papers by Seguin and Dalton in the *Medical Record* (1881). The "new phrenology" has been proved a valuable aid to diagnosis by the former, who has found Ferrier's statement of localizations to be, "not theoretical guides, but valuable life laws." The experiments of Dalton go to corroborate the position of Ferrier, that the angular gyrus is the seat of visual perception, blindness following its excision in dogs.

Allusion was made to numerous cases on record of abscesses of the hemispheres which have been diagnosticated by the local paralytic symptoms. The skull has been trephined, the abscess evacuated, and recovery has followed the operation. It is worthy of note, too, that Dr. Hughlings Jackson, reasoning from clinical and pathological observations of unilateral and localized epileptiform convulsions, formulated in advance of any experiments of Fritsch and Hitzig views of the ætiology of these convulsions, which are found to be in accordance with Ferrier's observations and those of his German predecessors. These obscure forms of epilepsy, referred by Jackson to irritative or discharging lesions of Ferrier's centres, are now known as "Jacksonian epilepsy." With regard to the various sensory centres (auditory, visual, gustatory, tactile, etc.) there is still great uncertainty; experimenters are not agreed as to the precise location of these centres in the cortex, nor as to the function of the occipital lobes.

Under his third head (psychical evolution, etc.) the essayist discussed the ancient phrenological hypothesis, which he considered unfounded and absurd. He advocated the evolutionary doctrine, which teaches — in opposition to the old view that mind is constituted by an assemblage of distinct faculties, having their seats in separate regions of the cerebral cortex — that "intelligence has neither distinct grades nor is constituted of faculties that are truly independent; its highest phenomena being the effects of a complication that has arisen by insensible steps out of the simplest elements." The only division of mind that has stood the test of the ages is the threefold division of intellect, feeling, and volition, and yet these three aspects of mind are, as Bain teaches, so dependent among themselves, although characteristic in their manifestations, that no one could exist alone, and feeling is the basic substance of mind. Intellect, moreover, is separable into only three factors: discrimination, or consciousness of difference; similarity, or consciousness of agreement; and retentiveness, or the power of memory or acquisition. The above being premised, it seems a necessary conclusion that identical parts of the brain are concerned in all the phenomena of mind.

The division of the cerebral hemispheres into lobes is artificial. There is everywhere intermingling of nerve fibres and nerve cells, and the closest blending of intercellular processes. The arrangements for diffusion of "nerve currents" are of the most perfect kind. Multiple as are the neural manifestations, there is practically, through all, the solidarity of a single unit.

The essayist, in taking up the subject of cortical centres with reference to a statement of Exner's modification of Ferrier's localizations, alluded to the views of Brown-Sequard and Goltz that the sensory and motor substrata of function are scattered over wide areas. This is possible by virtue of the well-known multiplicity of fibre connections, but improbable, and it presupposes the occupancy to a greater or less extent of a whole cerebral hemisphere by any voluntary operation.

There are strong considerations which favor the theory of localizations in limited areas of the cortex. In this seeming chaos of cells and fibres there must be orderly arrangement. If the cerebral hemispheres be a representation of inner relations answering to the most stable relations of the external cosmos, the order in the inner world must correspond with the order without. The law of physiological distribution of labor must apply to the cerebrum as well as to other parts of the economy. When you move your hand in obedience to a voluntary impulse, such motor excitation comes from a definite region of the cortex. It will always under similar circumstances come from the same cortical region. The fibres of the corona radiata which carry visual impressions to the cortex must pursue a definite route. Other sense impressions must follow, as it were, a beaten track to some region of the gray matter near the surface, when they are for a time concentrated, to be afterward, it may be, widely diffused, and blended with fibres of different sensory nature, and motor fibres. That the visual, auditory, and tactile centres occupy a wide area of the cortex seems probable when we consider the part which they have in building up the fabric of our mental experiences.

These opinions are in harmony with those expressed by H. Charlton Bastian in the "Brain an Organ of Mind," and other authorities. Bastian, who charily and reservedly admits the doctrine of localizations as applied to topographically distinct foci of sensation, while admitting the essential facts of motor localizations, was the first formally to propound the theory of "Perceptive Centres in the Cortex" in the *Journal of Mental Science*, 1869; also to state the view, supported of late by Exner, "that there may be much and compound overlapping of areas, and though the area pertaining to the impressions of any particular sense in the cerebral hemispheres may be a very extended one (not to speak of the still further complication brought about by the communication established between the nerve cells of the sense area with those of others in the same hemisphere, and the opposite hemisphere), still it may well be that certain portions of the surface of the cerebral hemispheres might correspond more especially to the *maximum* amount of nerve cells and fibres pertaining to some one or other of the various senses."

This theory of the overlapping of sense centres in the cortex and the wide diffusion of their cellular and fibrous connections has received striking confirmation from Exner's studies, to which attention was called in an editorial article in the *Medical Record* for April 15, 1882. According to Exner the cortical centres are rather areas of functional concentration than sharply demarcated sensory and motor foci, and the diffusion and interblending of fibres which there occur and the overlapping of one district by another afford a plausible explanation of the different results which have been noted in lesions of these districts, also of the recovery from functional paralysis which in animals so often

follows such lesions. In other words they are "vicariating areas."[1]

The cortical field of vision, according to Exner, corresponds more exactly with the region assigned to this sense by Muhr and Monk than to that assigned to it by Ferrier, namely, the angular gyrus. This perceptive centre has a relatively wide area in the upper and middle occipital lobes, extending thence into the cuneus. Here again Bastian's view is justified. According to Exner's observations the tactile fields correspond very closely with the motor fields for the same body regions, and this is in striking confirmation of the studies of Betz and Luys on the functional significance of the cells in the stratified zones. Luys believes that the submeningeal region, principally occupied with small cells, is especially connected with the phenomena of sensation, while the deeper regions, occupied by large cells (triangular cells of Luys, giant cells of Meynert), may be considered as the most important regions that give rise to motor phenomena. In studying this question Luys bases his conclusions principally on data acquired from a study of the spinal cord, which show that the regions of small cells have sensory functions (posterior cornua), while the regions of large cells (anterior cornua) are motor. Betz's special contribution to this micrographical study is that the large, so-called motor cells predominate in the neighborhood of the fissure of Rolando (Ferrier's excitable motor region).

The essayist in concluding remarked as follows: —

"On the whole the doctrine of localizations as propounded by Ferrier, with some probable modifications as above indicated, seems likely to be triumphant along the whole line.

"The question now presents itself, What is the explanation of this doctrine? What theory will best string together all these facts?

"The cerebral hemispheres, gentlemen, are, if we read comparative anatomy aright, a budding forth, an outcropping of the opto-striate bodies, the great sensori-motor ganglia; they are certain stories, as it were, added on to basal ganglia, and were called by Solly the hemispherical ganglia. The enormous augmentation of cells and fibres which compose these cortical centres bespeaks in the organism a higher and more complex system of adjustments of inner to outer actions, an extension of the correspondence in space and time, involving an increased amount of life and a longer continuance of life. Accumulating experiences in the race caused augmented development of the anatomical substratum representing those experiences, with its elaborate system of connections whereby those experiences are compared, and become combined and coördinated.

"I wish to be understood as hypothecating an immanent divine force raising matter through evolution to the sublimest organic plane, and developing out of the lowest nervous activities the highest powers of mind.

"I desire now to insist on the following points in elucidation of this difficult subject: If the cerebral hemispheres be an extension of the basal ganglia then the functions of these hemispheres cannot be essentially different from the functions of the basal ganglia. Assuming this we should expect, *a priori*, to find the same orderly arrangements for motor coördination in the cortex as we find in the lower ganglia, and as there is progressively an increase in the complexity of coördinations as we ascend the cerebro-spinal axis, so we are warranted in regarding the cerebral convolutions as the highest centres of muscular combinations, representing on a larger scale the combinations of the lower centres. Such being the case, as there are tracts in the inferior portions of the cerebro-spinal axis whose lesion causes local paralyses, so we should expect to find definite areas in the cortex whose lesion also would cause paralysis of a more or less local and limited nature. I have already shown that the facts are in harmony with this view. The gray matter in the neighborhood of the fissure of Rolando with its fibrillary prolongations in the corona radiata seems to contain the centres through which the will (I use this old metaphysical term to avoid circumlocution) acts downward on the corpus striatum, calling into play new cell combinations and the appropriate motor mechanism.

"With respect to the sensory and perceptive functions of the basal ganglia, called the sensorium by Dr. Carpenter, I would regard the cortical centres as simply the complement of those basal centres. Much confusion has been introduced into cerebral physiology by endeavoring to make an essential difference between the intelligential functions of the cerebral hemispheres and those of the sensorium, so called. The difference is only one of degree, not of kind. Luys is undoubtedly right in making of the optic thalamus a perceptive centre, in opposition to Dr. Carpenter, who considers it the centre of brute sensation. Every sensorial impression is to some extent *perceived* in the thalamus, although the elements constituting the complete perception of an object are largely supplied by the cortex. I would, then, style, after Luys, the sensory portion of the cortex the centres of augmented and completed perception. Such being the case I see no difficulty in understanding how the seats of common sensation and of special sense in the thalamus should have their representatives in the hemispheres. It may well be, moreover, that these cortical centres by education and development do finally in the highest creatures acquire such predominance that without their coöperation every sense impression shall be confused, unreal, or even *nil*. Hence the blindness that follows destructive lesion of the angular gyrus, and which in the lower animals is said gradually to be recovered from, probably by, the lower sight centre, which Luys locates in the thalamus, gradually taking on increased function. These are abstruse subjects, a provisional solution of which must for the present be sought in deductions from the general doctrine of evolution, which is shedding so much light on all difficult physiological problems."

[1] This view (of overlapping and diffusion) does not seem to me to be essentially different from that advocated by Dr. Hughlings Jackson in his recent Croonian Lectures. "It may be said that one convolution will represent only the movements of the arm, another only those of speech, another only those of the leg, and so on. The facts show that this is not the plan of structure of the nervous system. Thus, to take an illustration, the external parts, x, y, and z, are each represented by units of the corpus striatum. But the plan of representation is not that some units contain x largely only, as x^3, others y largely only, as y^3, but that each unit contains x, y, and z; some, let us say, as x^3, y^2, z; others as x^2, y^3, z, etc. When we come to the still higher evolution of the cerebrum we can easily understand that if the same plan be carried out a square inch of convolution may be wanting without palsy of the face, arm, and leg, as x, y, and z are represented in other convolutions, and we can also easily understand that discharge of a square inch of convolution must put in excessive movement the whole region, for it contains processes representing x, y, and z with gray matter in exact proportion to the degree of complexity." This doctrine of compensation, Dr. Jackson thinks, applies to representation of movements in the mid cerebral region of dogs. Destruction of a part of the dog's mid cortex entails no permanent paralysis, but discharge of any part of it produces convulsion. — *London Lancet*, April 26, 1884, page 743.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. W. SWAN, M. D., SECRETARY.

NOVEMBER 10, 1883.

THE MEDICAL TREATMENT OF UTERINE FIBROIDS.

Paper by DR. BLAKE.

DR. CHADWICK gave corroborative testimony as to the danger of removal of mural fibroids when of any size, — that of a billiard ball, or larger. He had removed a number, but considered them a very dangerous class of cases. One, which he had occasion to remember, was that of a very stout woman, with a sessile fibroid, not projecting into the uterine cavity, extremely hard, enucleable only as far as the fingers would reach, namely, only two thirds of its whole connection. The fingers and scissors could not be used together for want of room, and finally the operation had to be abandoned. This was at one P. M. At four P. M. a tremendous chill occurred, and an intra-uterine antiseptic douche was administered. The pulse and temperature nevertheless jumped up, more chills occurred, and twenty-four hours after the operation the woman died from septicæmia. The autopsy showed a tumor two thirds the size of the fist, its surface gangrenous. The liver looked like bread, it was so full of gas.

Two or three weeks afterwards Dr. Chadwick operated upon another case, and succeeded by digging and pulling and cutting in cleaning out all the growth in the course of an hour. Septic poisoning took place, and was arrested only by the intra-uterine douche of permanganate of potash. The disease was fought for two or three weeks, and the patient finally pulled through. Dr. Chadwick said he would not again undertake a similar case without the alternative of performing abdominal section in case the tumor could not be extracted. Dr. Chadwick referred to cases in other hands with similar results. He had found it difficult to dilate the cervix sufficiently for the operation, even with the aid of two or three successive batches of tents.

DR. SINCLAIR said he had never had a death following the operation of removal of a fibroid tumor; but might have had, and had seen death ensue from the operation in other hands, and considered it especially dangerous if any part of the tumor was left behind. Such a growth was infinitely more difficult to remove than an ovarian tumor.

DR. CURTIS spoke of the advantage in many cases of fibroids of tiding the patient along and waiting for the assistance of nature, even if there was serious hæmorrhage to call for interference. He recalled several cases of women who with such growths had been so treated, and were now able to walk or ride and enjoy comparatively decent health.

DR. LYMAN quite agreed with what had been said. He suggested the propriety in such cases of going back to the original proposition of Atlee, — the first man who ventured, forty years ago, to incise the fibroids, — a long free, but not deep, incision of the capsule, after which there was a much greater chance of expulsion by the use of ergot. The chief danger to be feared in this was sphacelus of the tumor and resulting septicæmia. Dr. Lyman had seen the operation of enucleation fail in the best of hands, and spoke of the difficulty of access to the tumor, the finger filling the uterine neck, after dilatation, more or less completely. Two methods only seemed to offer any really satisfactory results, namely, ligation of the tubo-ovarian artery on either side, as proposed by Mr. Thornton, thus diminishing the circulation in the organ; and, secondly, the removal of the whole uterus, although this operation we know had been attended with immense mortality in Continental hands, but Mr. Keith's results were encouraging. Fibroids easily enucleable were extremely rare. The two chief objections to the operation were its length, and the amount of laceration of tissue exposing the patient to the almost certain supervention of septicæmia.

DR. CHADWICK observed that there was one method of cure which had not been referred to, — pregnancy. In every case of a dozen or fifteen of this sort in his own experience the result of the supervention of pregnancy had been the complete disappearance of the tumor during involution and after parturition, and in all these cases but two the labors had been easy and natural.

DR. LYMAN said he was inclined to take the opposite view from that of Dr. Chadwick, and thought it very fortunate that women with such tumors did not generally get pregnant. If a uterine fibroid diminishes during involution so may it take on an increased size during evolution. Dr. Lyman quoted Dr. Thomas, who thought it a great misfortune for a woman with uterine fibroid to become pregnant. Dr. Lyman inquired of Dr. Chadwick the grounds for his position.

DR. CHADWICK replied [to Dr. Lyman] that his statement was based on his own experience, which he knew to be at variance with the commonly accepted views.

DR. LYMAN remarked that the woman was very likely to miscarry, in which case the liability to unfortunate complications must be greatly increased by the presence of a fibroid in the organ.

DR. SINCLAIR said he regarded Dr. Chadwick's view as correct, but had considered those cases which had disappeared during involution as sub-peritoneal.

DR. RICHARDSON said he would agree with Dr. Chadwick in part, in part differ. He had seen several cases of intra-mural fibroid which had disappeared as the result of pregnancy, although they were liable to occasion miscarriage, and had apparently in some cases been the cause of bad post-partum hæmorrhages. If the tumors have their origin near the placental site an irregular contraction of the uterus is liable, including the placental region, interfering with the proper closure of the uterine sinuses. In four of six or seven cases post-partum hæmorrhage had occurred. In three of the four it had been necessary to remove the placenta by hand to aid in arrest of the hæmorrhage, and in all these the tumor was under or near the placenta.

DR. FORSTER, on the question of the influence of pregnancy in causing the removal of fibroids, remarked that in a case of an extra-mural tumor under his care, which Dr. Baker had seen in consultation, the latter had advised that a contemplated marriage be consummated, as a pregnancy following might cause the disappearance of the tumor.

DR. CHADWICK, in reply to questions, could not state whether the tumors in the cases referred to by him were intra-mural or sub-peritoneal, a point which could not be determined after the pregnancy had advanced two or three months, as was the case when he first saw his patients.

Dr. Sinclair questioned whether there were not more or less of a pedicle in Dr. Chadwick's cases.

Dr. Chadwick said that there was no pedicle in his cases.

Dr. Richardson stated that he had seen two cases with pedicles, in both which pregnancy resulted disastrously.

Dr. Elliot observed that the sense of the meeting seemed to be that mural fibroids should not be removed on account of the danger of septicæmia. He had seen several removed successfully. The cases cited showed how dangerous such may be. They should make us more careful about antiseptic precautions, but should not deter one from performing the operation. He thought that a more antiseptic operation would give better results than the cases here reported. The largest tumor of the kind he had seen was removed by Schroeder, and it was so large that it was difficult to pull it through the pelvis; the cervix was not only dilated, but slit on either side; the operation was done under full antiseptic precautions. Dr. Elliot himself used plugs to dilate the cervix, and had found no difficulty in accomplishing this, which, if not sufficient, could be augmented by slitting the cervix. Moreover, the dilatation improved under the manipulation.

PUERPERAL CONVULSIONS.

Paper by Dr. Blake.

Dr. Blake referred to the cases of Dr. Staples, of Dubuque, all cured by the subcutaneous injection of veratrum viride. In his own [Blake's] cases no morphia was used.

Dr. Homans stated his belief that patients generally get well of convulsions unless these were apoplectic or there were disease of the kidneys; seventeen cases out of twenty recovered. The majority of ordinary cases were hysterical.

Dr. Richardson asked Dr. Homans whether he would terminate the labor in a case of ante-partum convulsions.

Dr. Homans referred to a case in which, convulsions occurring at the seventh month, the patient was treated with rest, ether, bromide of potassium, and went on to full term and a natural labor.

Dr. Richardson said he was glad to hear that Dr. Blake put his reliance on chloral rather than morphia. He had seen forty-three cases of puerperal convulsions, and the only two that died were the only ones which had been bled. There were cases undoubtedly in which bleeding was the best treatment. In Dublin this summer he had observed that the practice was to do nothing, — let the woman alone, — but it had seemed to Dr. Richardson that by this course patients there had been lost which might otherwise have been saved. Cases that come on post partum, Dr. Richardson remarked, are of a very grave character.

Dr. Homans said that when he first began to practice, if the woman was swollen and flushed, it was the practice to bleed.

Dr. Edes quoted Dr. C. C. P. Clark as saying that every case of convulsions should get well if treated by the subcutaneous injection of morphia to the amount of three grains at once. He wished to know whether the Obstetrical Society had any experience with such large doses.

Dr. Lyman said that it was the practice in New York to administer morphia, but he had never heard of the large dose in that connection.

Dr. Richardson stated that he had used as much as two grains of morphia, but thought chloral was much better, and left the patient in a better condition. When the convulsions came on he used ether, but chloral regularly. Dr. Richardson asked if any one had seen a convulsion occur when the patient was completely etherized.

Dr. C. Ellery Stedman said he had seen one case occur, and he believed the etherization was complete.

Dr. Blake objected to the use of morphia in these cases on the ground that it was liable to impair the activity of the kidneys.

Dr. R. B. Dixon exhibited two instruments of his own invention, a trephine and a blunt hook and knife combined.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

C. B. Nancrede, M. D., Recorder.

Thursday evening, May 23, 1884. The President, Dr. Tyson, in the chair.

A CASE OF PAGET'S DISEASE.

Presented by Dr. W. G. Macconnell for Dr. Jos. Hearn.

This breast was removed at the Jefferson College clinic by Dr. Hearn, Saturday, May 17, 1884. History: Mrs. Baker, aged thirty-nine years, has been married for nineteen years, and has borne four children, and has had one miscarriage. No other member of her family has ever labored under any form of tumor. Four years ago, following a pustular eruption which she observed on her abdomen, a lump was noticed in the left breast, which was the seat of a lancinating pain of an intermittent character. Previous to the discovery of the lump an eruption of an eczematous nature was noticed; it had existed some seven or eight months before she noticed the lump. The nipple, at the time of the operation, was thoroughly retracted, indeed, had melted away. There was no axillary involvement, although there was noticed a gland at the upper and inner quadrant of the breast. On section of the tumor after its removal several small nodules of a hard, fibrous consistence were encountered. Microscopically I found them to be the seats of carcinoma of a scirrhous nature. The gland revealed a similar condition.

COLLOID CARCINOMA.

This tumor was removed by Dr. Hearn at the Jefferson Medical College Hospital, about one week previous to the removal of the other breast. History: Miss Catharine Brooks, aged sixty-seven; general health good; family history that of phthisis. No other member of her family had ever labored under any form of tumor. About three years ago she felt a lancinating pain in the right breast. On examination she found a lump, which was hard, roundish, and about the size of an English walnut. It continuously tended to increase, when, at the end of eighteen months, it had attained the size of an egg. She consulted a quack, who applied a salve, which she states caused some bleeding. Two months before her admission to the hospital she states that the breast began to "gather," and one week previous to the operation "it broke, and a dark greenish fluid escaped," which was afterwards followed by the extrusion of a mass of greenish-colored slough.

The growth was attached to the overlying skin, but not to the pectoral tissues beneath; the subcutaneous veins were enlarged and prominent; no glandular involvement existed. On section the tumor was found to be densely hard, and the seat of small cavities filled with a glairy, gelatinous, semi-solid fluid. Microscopic examination showed alveoli filled with epithelium that had undergone fatty degeneration, not a few of them showing the peculiar laminated appearance peculiar to colloid. The connective tissue of the stroma was in a state of active proliferation, due, probably, to the inflammation resulting from the cystic change already mentioned.

SARCOMA OF TESTICLE.

Presented by DR. G. DE SCHWEINITZ.

This growth was removed from S. H., aged thirty-seven, married, a patient of DR. JOHN ASHHURST, in the surgical ward of the University Hospital. His father and mother are living, and in good health. His grandparents died in old age, having led healthy lives. Of his two brothers and two sisters all are living, and three of them have been thus far in good physical condition. One sister had a growth removed from the orbit, probably a sarcoma, which is now beginning to recur. His own health has been good. He denies any venereal disease. Two and a half years ago he first began to notice a globular swelling at the bottom of the left testicle, which gradually increased in size until eight months ago, since which time the growth has been rapid, so that at the time of operation the circumference of the testicle measured fourteen and a half inches. Pain has been insignificant until last April, since which time he has suffered with severe dragging pains. The inguinal glands on both sides were slightly enlarged. The growth occupies the body of the testis, being surrounded by the tunica albuginea and tunica vaginalis, which are intact. It is a large, somewhat irregular, moderately soft, blood-stained mass. In one end there is an area of cystic degeneration. Microscopic examination shows this tumor to be a sarcoma of the round-cell variety, the cells being moderately large, containing oval nuclei or sometimes nucleoli. In places a faint reticular net-work is demonstrable, producing a picture similar to the "lymph-gland like" round-cell sarcomas.

PHILADELPHIA CLINICAL SOCIETY.

G. BELTON MASSEY, M. D., RECORDING SECRETARY.

STATED MEETING, MAY 23, 1884. DR. HENRY BEATES, JR., in the chair.

DR. MARY WILLETS reported a

PUERPERAL CASE WITH NUMEROUS COMPLICATIONS.

Mrs. H., aged thirty, primipara, after a normal delivery did well for twelve days. Then, after pain in her back and limbs and chilly sensations, had a rise of temperature, and was attacked with nausea and vomiting. The temperature continued high for two weeks. There was nothing to account for the supra-normal temperature except a laceration of the cervix uteri and some tenderness around this point. On the twenty-fifth day after delivery the patient complained of pain in her left leg. For more than a week there was pain and swelling both above and below the knee; the pain greatly increased on pressure and attempted extension of the limb, and was in the course of the femoral vein, but careful examination failed to discover anything abnormal. On the forty-third day, the patient having recovered sufficiently to go down stairs, we were suddenly confronted with well-developed mania, at first violent, but subsequently becoming merely loquacious. This continuing two days gave place to somnolence, and five days later to convalescence.

DR. E. E. MONTGOMERY remarked that the case was unusual from the lateness at which the fever appeared. During his present term at the Philadelphia Hospital measures had been instituted to prevent the contact of septic matter with the parturient parts. A solution of corrosive sublimate, one to two thousand parts, was used to sponge the parts after placental delivery, and cloths saturated with the solution were kept in place by absorbent cotton, oil silk, and a tail bandage. There had been but three cases of septicæmia during the present quarter.

DR. A. H. SMITH said the local examination which the reader of the paper had very properly made solved the whole problem. Together with the symptoms it showed the case to be one of pyæmic — not septicæmic — poisoning in a woman feeble and unable to resist the absorption of pus. Septicæmia cannot arise after all open surfaces have become purulent. The examination was valuable, and he thought it would be better if more care was generally exercised in this direction.

DR. PHILIP M. SCHIEDT read a paper on the

CLINICAL PHENOMENA FOLLOWING THE PUERPERAL STATE IN TWO CASES.

In the first case he was suddenly summoned to the bedside of a woman aged about thirty-five, whom he found comatose, with undilated pupils, head drawn to left side, and flexed on the chest, a clammy sweat on forehead, and imperceptible pulse. The heart sounds were faintly detected, and the body and extremities warm. Restoratives and artificial respiration were without avail, and the patient soon expired.

The history of the case, subsequently ascertained from the family physician, was as follows: She had been delivered of a child after a natural labor two weeks previously, which was followed by a normal convalescence unaccompanied by fever or offensiveness of the lochial discharge. Her babe was healthy, was regularly nursed by her, and she was doing so well that her physician had ceased his visits. On the morning of her death she felt unusually well, but about nine o'clock complained of some headache, vomited a little mucus; had a heavy chill; became unconscious, and was found by me in the condition described, which soon terminated in death.

The notes were presented to the Society for the purpose of obtaining the opinions of its members as to the cause of death, the writer expressing a belief in its cardiac origin.

The other case was one of

TEMPORARY BLINDNESS FOLLOWING LABOR.

After a perfectly natural labor, three hours in duration, the mother failed to see her child when presented by the nurse. It was found that she was perfectly blind and unresponsive to the candle test. She remained fully conscious and in possession of other senses. This continued three days, and was followed

by gradual and complete recovery. During this time there was nothing otherwise abnormal in her condition. There was no œdema, therefore no examination of the urine was made. Previous to confinement she had been well able to attend to her duties.

Dr. L. Brewer Hall, in discussing the second case, said the most plausible explanation of such rapidly disappearing blindness was œdema giving rise to choke disk. The cases reported have not been properly examined by an ophthalmologist, an omission frequently inexcusable. Some cases do not get well, and then we find an atrophy of the optic nerve. He had seen quite a large number of hysterical cases, at times monocular, and such cases are easily diagnosticated by feints and attempts to discover that they do see while off their guard. Some one should always be called in in these cases to make an ophthalmoscopic examination.

Dr. Albert H. Smith acknowledged the want of exact information, while the uræmic origin of such cases had been assumed.

Dr. G. Belton Massey denied the necessity of assuming that cases of hysterical blindness were mere malingerers. Such patients at times may be perfectly honest in their inability to see, the real condition being one of divorce between the volitional and intellectual powers of the mind.

Dr. E. E. Montgomery read a paper on

TRACHEOTOMY IN CROUP AND DIPHTHERIA

based on an experience of twelve cases, one of which, a case of diphtheria, had recovered, and was exhibited to the Society. Five of the operations were for diphtheria, the remainder for croup. In all the operation was one of last resort, and the series teach the importance of early operation. Death occurred most frequently between the third and fourth days; one died in fifteen hours, a second in thirty-six hours, and another on the ninth day. In the successful case the canula, owing to laryngeal spasm, remained until the twenty-fourth day. In operating he gives chloroform, and avoids hæmorrhage by transfixing a fold of skin, held by himself and assistant, making an incision 1″ long, completing the dissection to the trachea by the forceps and grooved director. After opening the trachea care is observed to remove all membrane previous to insertion of canula. After-treatment consists in attention to tube, keeping several thicknesses of tarlatan wet with hot carbolized water over it. The temperature of the room is maintained at between 75° F. and 80° F., and stimulants and good food given together with quinia, tincture ferric chloride, and corrosive sublimate, the latter in frequently repeated doses. The attempt is made to dispense with the tube from the fifth to the eighth day, but it should not be removed until respiration *per vias naturales* is fully established. From these cases he draws the following conclusions: (1.) That tracheotomy is justifiable in diphtheria as well as croup. (2.) That it should be performed in croup when it is evident that drugs do not control the progress of the disease, particularly when there is depression of the lower end of the sternum during inspiration; in diphtheria with the advent of suffocative symptoms. (3.) That in the performance of the operation the knife should only be used to incise the skin and trachea, the intervening tissue being torn by director and forceps. (4.) That the subsequent use of proper drugs will promote a favorable result.

Dr. Collins recalled several flattering cases which in a few days showed crape on the door. He doubted the propriety of anæsthesia, but thought the operation justifiable if only as a means of easing death.

Dr. William H. Parish said this operation, which was one of the easiest in performance, should be resorted to whenever the symptoms were of such a character as to show impending suffocation. To determine this required no little judgment, and he recalled a case of recovery without operation where both himself and Dr. Allis had agreed it should be performed. He treats diphtheria by large doses of chlorate pot. and iron.

Dr. W. H. Warder, in discussing the treatment of diphtheria, thought the chlorate of potash and tincture ferric chloride most successful in ordinary cases. In more malignant ones had resorted to calomel in five-grain doses. In a case which Dr. Pepper had seen with him the latter advised a continuance of this plan for forty-eight hours. At the end of this time forty grains had been taken. A large and offensive evacuation followed, and the child recovered. He did not think such large doses usually necessary, however. Much of the calomel passed without other change than oxidation.

Recent Literature.

Malignant Disease (Sarcoma and Carcinoma) of the Larynx. By Henry T. Butlin, F. R. C. S., Assistant Surgeon and Demonstrator of Diseases of the Larynx, St. Bartholomew's Hospital. London: J. & A. Churchill.

This little book will prove of value not only to laryngologists, but to all interested in the life-history of the malignant growths of which it treats. The author has already published a work entitled "Sarcoma and Carcinoma," of which the monograph before us may be considered a continuation. In the former work Mr. Butlin studied malignant disease as it affects the bones, œsophagus, tonsils, etc., while in this essay he confines himself to sarcoma and carcinoma as they occur in the larynx. The most important outcome of the inquiry, as the author says, is the discovery of the influence which is exercised over the whole course of a malignant tumor by its origin. To be convinced of this fact one need only compare the course of central with subperiosteal sarcoma of bone, of sarcoma of the breast with sarcoma of the tonsil, of squamous carcinoma (epithelioma) of the lip with squamous carcinoma of the tongue. The importance of the local study of these diseases on a larger scale than heretofore is insisted upon. The larynx is well suited for such a study, and the author's labors result in showing the wide difference which may exist in the course pursued by sarcoma and carcinoma of the same organ, and how even carcinomas arising from different parts of the same organ pursue habitually a very different course even when the structure of the tumor is the same. The cases reported number seventy-three, of which twenty-three are sarcomas and fifty are carcinomas. It is pointed out that this difference does not show the true numerical relation which exists between sarcoma and carcinoma of the larynx, for carcinoma is so common that individual cases are not usually published. The author has excluded all cases in which a

microscopic examination has not been made. Krishaber's division of sarcoma and carcinoma of the larynx into intrinsic and extrinsic has been adopted. Intrinsic sarcoma of the larynx rarely, if ever, affects the lymphatic glands or becomes disseminated. The author thinks that the obstacle to glandular affection is mechanical, and suggests that as the cells proliferate the solid structures gradually swell, and the lymphatic vessels suffer a diminution of their calibre, which proceeds to their complete obliteration, and renders them incapable of transmitting the infecting material of the tumor. Before attempting any treatment we must be sure of the diagnosis, which is best accomplished by removing a portion of the growth by the intra-laryngeal method with forceps, and subjecting it to microscopical examination. Intrinsic sarcoma, even in advanced cases, may be successfully treated by complete removal of the part from which it grows, which may necessitate partial or complete extirpation of the larynx. Extrinsic carcinoma infiltrates deeply, and affects the lymphatic glands early. Attempts at removal even by extirpation of the larynx and the neighboring glands afford not the slightest prospect of success or even of temporary benefit. Intrinsic carcinoma is a much less formidable malady. In cases in which the disease is limited to the cavity of the larynx, and the glands are not affected, partial or complete extirpation of the larynx may be performed. But if the disease has spread beyond the larynx, or there is enlargement of the glands, the prospect is almost as hopeless as in cases of extrinsic carcinoma.

Cases, whether of sarcoma or carcinoma, which appear unsuited for a radical operation of whatever kind may often be greatly benefited by an early tracheotomy.

Dictionnaire Annuel des Progrès des Sciences et Institutions Médicales. Par P. GARNIER, Médicin, etc., etc. Dix-neuvième année, 1883. Paris: Felix Alcan, Éditeur: 108 Boulevard, St. Germain. 1884. 501 pages. 12mo.

This very useful volume comes to us rather late though it may have been issued with due punctuality. It is a kind of French Braithwaite, with this essential difference, that it gives abstracts, not extracts merely, and marks out what of value an article contains, or wherein an advance has been made.

Next year, the twentieth of the series, the author promises a complete index which will be of great service to any one seeking what has been gained in any medical matter during the last twenty years.

In his usual summary of the last year's work the author gives due prominence to the labors of the microscopists. To such a degree have their activity and efforts been lately absorbed in the search and discovery of organisms attendant upon diseases, that he appears to think that the year 1883 will figure grandly in the annals of medicine on its millennial anniversary should the capital work done in it for tuberculosis justify the predictions already announced. For ourselves, however, we cannot fully anticipate for posterity such a "happy return of the day." To our mote-obscured vision these bacilloids appear to be great *beams* in the eyes of experimenters, rather than efficient causes of disease. So far as proof goes at present they seem somewhat analogous to larvæ which sometimes infest exposed ulcers, or pus-secreting surfaces. We beg pardon, hardly hoping, in these days of irreverence for the infinite and the infinitesimal alike, for forgiveness for such evidence of unreclaimed Philistinism. We refer the reader to the *Dictionnaire*.

Time and space will not allow of further notice of this Annual at present. Every one who wishes a ready reference book for what has been going on in the medical world during the period of its existence should have a copy at hand. *

The Veins of the Brain and its Envelopes. Their Anatomy and Bearing on the Intra-Cranial Circulation. By WILLIAM BROWNING, M. D., Brooklyn. Brooklyn, N. Y.: F. B. O'Connor, Jr. 1884.

The first sixteen pages of this monograph appeared in the *Annals of Anatomy and Surgery*, now unhappily defunct, so that the author was obliged to publish as a thick pamphlet what was apparently meant to be a series of articles. We are glad he has done so, for it presents the results of much careful work of a kind that is carried on too rarely among us. Indeed, the anatomical part of this paper is the record of work done in Professor Braune's laboratory at Leipsic. The veins of the brain were carefully injected, classified, and described. The work is done in a thorough manner, and the book before us is very much the best authority we know of for the anatomy of the intra-cranial veins. The author, moreover, shows himself familiar with the literature of the subject We are inclined to think he hardly does Rüdinger justice in the question of the originality of his views on the Torculæ. The work is necessarily of the driest, and little can be well extracted for special mention, but we must allude to the important discovery that the common views of the great vein of Galen are incorrect. It is usually described as running backwards into the straight sinus; in point of fact it winds up behind the splenium of the corpus callosum, and runs forward before turning back to join the sinus. The English of this paper leaves a good deal to be desired, the construction and idioms are so evidently German. It shows, however, German method and industry, and is of real value. T. D.

Female Hygiene and Female Diseases. By J. K. SHIRK, M. D. 12mo, 107 pages. Lancaster, Pa.: The Lancaster Publishing Co., 1884.

This book is intended for the "instruction of the laity": it gives some good advice on matters of hygiene, and some that is, to say the least, questionable, *e. g.*, on page 16, that "every civilized woman should rest in the recumbent posture during a good part of every menstrual period." If however the author had confined himself to this part of his subject, his book might have been productive of good results; but he has attempted to describe in popular language the various diseases of women, their symptoms and causes, and has given advice and prescriptions for their treatment: this part of the book we believe will be productive of harm. No woman is the better, in our opinion, for knowing anything about her ovaries or fallopian tubes: nor do we believe it expedient to instruct the laity how to treat amenorrhœa. The author's motives in writing the book we do not question; but we cannot approve of the class of books to which this belongs.

THE EIGHTH INTERNATIONAL MEDICAL CONGRESS.

THE programme of the next International Medical Congress, which is to be held at Copenhagen in August, has just been issued. The session will open on Sunday, August 10th, and close on Saturday, August 16th. The programme as published contains a list of papers promised and subjects to be discussed, but the definite programme of each day's work has not been made public. As on previous occasions the official languages are to be French, German, and English. The addresses in the general meetings are to be given by Professors Virchow and Pasteur, Sir William Gull, Professors Tommasi Crudeli, of Rome, Verneuil, of Paris, and Panum, of Copenhagen. Sir William Gull will speak on behalf of the Collective Investigation Committee of the British Medical Association on International Collective Investigation of Disease.

There are to be fourteen Sections: Anatomy, Physiology, General Pathology and Pathological Anatomy, Medicine, Surgery, Obstetrics and Gynæcology, Ophthalmology, Pediatria, Dermatology and Syphilis, Psychiatria and Nervous Diseases, Laryngology, Otology, State Medicine, and Military Medicine. Certain of these Sections are to hold joint meetings to hear papers and consider certain subjects that equally concern both divisions. The Sections meet daily from ten to twelve and from one to three. The general meetings will be held from four to half past five, with some extraordinary assemblies in the evening at eight. The work laid out in the Sections gives promise of little leisure. The subjects chosen cover a wide field, and embrace most of the matters in which special interest has been shown of late.

The prominent position in the Congress of matters relating to bacteria, the germ theory and its applications, is very noticeable. Professor Pasteur's Address before the general meeting is to be on Morbific Micro-Organisms and Vaccine Matters. In the Section of Pathology Professor Chauveau, of Lyons, will consider the Tuberculosis of Domestic Animals as a Source of Human Tuberculosis. Professor Bang, of Copenhagen, will read a communication on Tuberculosis of Cows' Udders and Inoculation with Milk from Tuberculous Udders. Koch will discuss the Variability of Pathogenic Bacteria, Cornil, of Paris, will consider the Transformations of Cellular Elements in an Inflammatory Focus of Bacterial Nature. Drs. Friedlaender, of Berlin, and Salomonsen, of Copenhagen, will respectively demonstrate the Pneumonia-Micrococcus and Cultures of Bacteria in Capillary Tubes.

In the Section of Medicine Professor Bouchard, of Paris, will present a communication on the Antiseptic Treatment of Acute Infectious Diseases; Professor Ewald, of Berlin, on the Ætiology, Diagnosis, Prognosis, and Treatment of Tuberculosis as Influenced by Recent Experiences in Pathological Anatomy and Experimental Pathology. In the Section of Surgery the Most Important Methods of Antiseptic Treatment of Wounds will be treated by Professors Lister, Mosetig-Moorhof, of Vienna, Paul Bert, of Paris, and Esmarch, of Kiel, and Dr. Schede, of Hamburg. In the Section of Gynæcology Professor Mikulicz, of Crakow, will present a communication on Antiseptics in Laparotomy; Dr. Rupprecht, of Dresden, will discuss the Choice of Antiseptics for Treatment of Wounds in Children; Dr. Unna, of Hamburg, will consider the Rôle of Micro-organisms in Skin Diseases not Formerly Considered Parasitic, and the Antiseptic Treatment of Wounds in Time of War will be considered by Professor Esmarch, Sir W. MacCormac, Dr. Neudörfer, of Vienna, and Dr. Strube, of Berlin.

The Americans whose names appear as authors of communications promised are not numerous. Prof. Austin Flint will present a paper on a Uniform Nomenclature of Auscultatory Sounds in the Diagnosis of Diseases of the Chest; Dr. Solis Cohen will consider the Prognostic Significance of the Several Local Manifestations Observed in Tuberculosis of the Larynx; Dr. Lefferts, of New York, will treat of the Removal of Foreign Bodies from the Larynx; Dr. Bosworth, of the Singing Voice, its Proper Method of Training; and Dr. French, of Brooklyn, of Photography of the Larynx; and Dr. J. Orne Green, of Boston, will read a paper on the Diagnosis of Intra-Cranial Complications in Suppurative Inflammation of the Middle Ear.

Not only is the scientific programme inviting, but the opportunity for a visit to so charming a capital as Copenhagen should lead to a larger attendance than the few Americans who have promised to take part in the exercises would seem to indicate.

A NEW LINE OF RESEARCH FOR CEREBRAL PHYSIOLOGISTS.

IT is one of the postulates of the new cerebral physiology that every member or organ has its representative centres in the hemispheres. The advocates of cerebral localizations have, with great definiteness, mapped out on the convolutions centres for movements of the eyes and mouth, extension or flexion of the arm and hand, complex movements of the thigh, leg, and foot, etc., and the organs of special sense, and even the viscera are believed to have an intimate relation with certain cell groupings in the hemispherical ganglia. The facts on which this doctrine is founded are already sufficiently known through the writings of

Ferrier, Charcot, and others. We wish to call attention to-day to one line of research which may possibly be fruitful in results of great corroborative value as far as the localization theory is concerned. If, corresponding to the members of the body, there are certain positive differentiated cortical foci, then must lesion of those members have some disturbing influence on their encephalic representatives, and suppression or removal of the former will be likely to be attended with atrophy of the latter. Facts confirmatory of this way of thinking are yet few in number. A case is recorded by Sander in *Centralblatt* for 1875, in which the loss of a limb was accompanied by marked wasting of the corresponding motor region of the cortex. Similar observations have now and then appeared in other journals. Some of these are, however, discordant, as is the case reported by Luys, where the atrophy occurred in a region of the cortex to which motor functions are not assigned.

Recently Raymond, of the Hôspice des Incurables, has communicated to the *Progrès Médical* the details of a case which is a contribution of some value on the positive side of the question. It concerns a patient aged thirty-one, who died in the Hôtel Dieu of tuberculous meningitis. Eleven years previously this patient had undergone amputation of the left arm at the shoulder. The meningeal tuberculous disease from which he died was consecutive to chronic pulmonary phthisis. The autopsy revealed the ordinary lesions of granular meningitis, but the striking feature, and that which makes it of interest in this connection, was the existence of pronounced atrophy in the right hemisphere of those very portions of the convolutions bounding the fissure of Rolando (ascending frontal and ascending parietal) to which have been assigned by Hitzig, Ferrier, and other recent experimenters the psycho-motor direction of the left upper extremity. The atrophy, it is true, was somewhat more extensive than the area pertaining to these centres, and the shrinkage of the superficial zones was more marked in front of than posteriorly to the fissure of Rolando, but the fact remains that there was found deficiency, as if by want of development or atrophy, of the supposed centres of all the movements of the left arm, forearm, and hand. No degenerative lesion or asymmetry of any other portion of the cerebro-spinal axis was noted.

It must be confessed that the evidential value of this observation, as of others of a like nature, needs qualification by the doctrine (if true) which has been formally stated by M. Féré, that the opposite lobes of the cerebral hemispheres are habitually asymmetrical.

THE ONE HUNDRED AND THIRD ANNUAL MEETING OF THE MASSACHUSETTS MEDICAL SOCIETY.

THE annual meeting of the Massachusetts Medical Society is still in progress as this number of the JOURNAL goes to press. We therefore defer any reports or comments for another week.

At an adjourned business meeting on Tuesday afternoon, about a quarter of the membership being present, it was voted, by a large majority, to admit women to examination by the Censors, a vote which was concurred in at the meeting of the Councilors in the evening, sixty-three voting in the affirmative and forty-seven in the negative. This action we believe to have been the result of somewhat mixed motives, but whatever the motives or the method the Society has committed itself, and we have simply to chronicle the results.

MEDICAL NOTES.

— In a recent communication to the Académie de Médecine M. Luys took novel ground as to the mobility, or rather the locomobility, of the brain. He believes that the cerebral mass is subject to the laws of gravity, and that an empty space occupies whatever portion of the cranium is uppermost at the time being, varying, of course, according as the individual is upright, recumbent, or inverted. In lateral decubitus, for instance, the falx cerebri is displaced, and the vacant space is between the skull and the temporal lobe. He believes that this movement does not take place suddenly, but occupies five or six minutes in being accomplished. In the following session of the Académie M. Béclard opposed the opinion pronounced by M. Luys. He thought that the word "movement" was badly chosen to represent what passes in the cranium, and would prefer "commotion" or a change in the volume of the cerebral mass, which after all was very limited, and to be explained by the number of vessels it contained. He himself could not accept the idea of total displacements as entertained by M. Luys, for there did not exist in the cranial cavity any space that was not occupied either by the brain itself, the venous plexus, or the cephalo-rachidian liquid. M. Luys, in replying, maintained what he had already advanced, and was followed by M. Jules Guerin and M. Collin, who were both in favor of the theory of cerebral displacement under the conditions already mentioned. The clinical bearings of this theory, if it shall become established, will be important with reference to the relations of position, and especially of changes in posture upon vertigo, syncope, and other symptoms referable to circulatory conditions inside the cranium.

— It is reported of Bishop Smith, the senior bishop of the Protestant Episcopal Church, who died recently at the age of ninety years, that besides never having used alcohol or tobacco he possessed the more unique distinction of never having taken a dose of medicine during his life.

— The will of Samuel W. Swett, late of Boston, has been filed in the probate court, and contains a large number of munificent public bequests, disposing of some $250,000 in charity. The will is dated December 14, 1880. Medical and hospital interests are generously remembered, as will be seen from the following list: To the Massachusetts Institute of Technology, $10,000; to the old men's home, Boston, $5000,

its corporate name being the Home for Aged Men; to the Massachusetts General Hospital, to aid that corporation in building and maintaining a hospital for convalescent patients, under such rules and regulations as the said corporation may think proper to make, the sum of $50,000, and in case the said corporation should not think it expedient to establish such hospital for convalescent patients, the income of the trust fund, or any part, or the whole of the fund itself may be used by said corporation in any manner the said corporation may think best for its interest; to the Boston North End Mission, $20,000; to the Missionary Society of Boston, $10,000; to the Boston Young Men's Christian Association, $5000; to the Young Men's Christian Union, $5000; to the American Board of Commissioners for Foreign Missions, $10,000; to the Provident Fraternity of Churches, $5000; to the Massachusetts Home Missionary Society, $10,000; to the Boston Provident Association, $10,000; to the Boston Marine Society, $10,000; to the Sailors' Snug Harbor, located at Quincy, Mass., $10,000; to the Temporary Home for the Destitute, located at Nos. 1 and 2 Pine Place, $5000; to the President and Fellows of Harvard College, for the use of the Medical Department, $20,000; to the Baldwin Street Home for Little Wanderers, $20,000; to the Boston Children's Aid Society, $5000; to the Children's Hospital of Boston, $10,000; to the New England Hospital for Women and Children of Boston, $10,000; to the Children's Mission for Destitute Children, $10,000.

NEW YORK.

— At the last meeting of the Academy of Medicine, held Thursday evening, June 5th, twenty-four new Fellows were admitted, and the President, Dr. Fordyce Barker (who has just returned from Europe), made an address in regard to the death of the senior ex-president, Dr. Willard Parker, and honorary Fellow, Dr. S. D. Gross. He also alluded in feeling terms to the bereavement of Dr. S. T. Hubbard, whose son, Dr. William H. Hubbard, recently died from disease contracted in the discharge of his duties as one of the house-staff of Bellevue Hospital, and resolutions tendering the sympathy of the Academy to Dr. Hubbard and his family were afterwards passed. Dr. R. W. Amidon then read a paper entitled A Plea for More Heroic Surgical Interference in Affections of the Brain, which was discussed by Drs. Garrish, Noyes, and Putzel, after which a resolution was adopted urging upon Governor Cleveland the signing of a bill recently passed by the Legislature, which provides for the purchase of suitable lands for a number of new parks in the upper part of the city. The Academy then adjourned to meet on the first Thursday in October.

— A clergyman temporarily residing in the city was summoned last week to appear in the Yorkville police court on the complaint of the Society for the Prevention of Cruelty to Children that he had permitted his daughter, a child six years of age, who had fractured her arm, to remain without medical attendance. He was a firm believer in the "faith cure," but when he learned that the Society was about to proceed against him he secured the services of two surgeons, and when he appeared in court was armed with a certificate that the child was being properly cared for, in consequence of which the complaint was dismissed.

— Dr. Thomas C. Chalmers, an old and highly respected physician of New York, died June 4th of uræmia, the result of cystitis and pyelitis. He was born at West Galway, Saratoga County, N. Y., in 1810, and was graduated with high rank from Union College in 1831. He received the degree of M. D. from the College of Physicians and Surgeons, New York, and was one of the original founders of the Academy of Medicine, of which he remained a Fellow up to the time of his death.

— The trial of James Brown, an ex-attendant, charged with manslaughter in the first degree for causing the death of Evan D. Hughes, a patient in the State Lunatic Asylum at Utica, in January last, was concluded on the 4th of June, resulting in the conviction of the accused of manslaughter in the second degree.

— The new buildings presented to the German Dispensary by the late Mrs. Oswald Ottendorfer were formally opened on the 24th of May. The principal address was delivered by Dr. A. Jacobi.

PHILADELPHIA.

— On Thursday evening, June 5th, a complimentary dinner was given by the profession of Philadelphia to Prof. Alfred Stillé in commemoration of his retiring from the chair of practice of medicine in the Medical Department of the University of Pennsylvania, a position from which he resigned at the close of the last session, after twenty years' service. Among the guests present were Dr. Stillé's life-long friend, Dr. F. C. Shattuck, of Boston, who shared his studies in Paris, Surgeon W. S. W. Ruschenberger, medical director United States Navy, now retired, Dr. Austin Flint, of New York, Surgeon J. S. Billings, United States Army, of Washington, and Traill Green, of Easton, Pa. Professor DaCosta presided in the place of Professor Gross, whose death had occasioned a postponement of the supper from the first time appointed. Seventy-seven covers were laid, and nearly all were present, including Drs. Agnew, Bartholow, Pepper, Brinton, Solis Cohen, Pancoast, Parvin, Tyson, H. C. Wood, J. Ashhurst, Hutchinson, Hays, C. Wilson, J. C. Wilson, S. Lewis, and many other prominent members of the profession. Addresses were made by Drs. DaCosta, Stillé, Shattuck, Billings, Pepper, and Flint. Letters of regret were received from Prof. Oliver Wendell Holmes, of Boston, John L. Atlee, of Lancaster, A. G. Moses, of St. Louis, Henry I. Bowditch, of Boston, and Edward Hartshorn, of Philadelphia. During the evening the chairman presented to Dr. Stillé an album containing the autographs of those present at the dinner. The whole affair was a memorable one, and was heartily enjoyed by all.

— Dr. William Pepper, formerly professor of Clinical Medicine, has been appointed to the vacant chair of

Practice of Medicine in the Medical Department of the University of Pennsylvania.

— Professor Gross having bequeathed his library to the Academy of Surgery of this city, it is understood that the bequest will be accepted, and a special deposit made of the books with the College of Physicians, where the Academy holds its meetings.

— At the June meeting of the College of Physicians, Dr. DaCosta took his seat as President, and in a few words thanked the College for the honor conferred. Dr. S. Weir Mitchell was unanimously elected Vice-President.

— At the quarterly meeting of the Philadelphia County Medical Society, held June 5th, an amendment made with a view of keeping out women candidates, by declaring that the Society shall consist of "male" members, was lost, having failed to get a two-thirds' vote. But a woman candidate was defeated as usual.

— The Point Airy Sanitarium, a health resort or park on Windmill Island, situated in the Delaware River, opposite the city, was opened June 5th. It was designed by some charitable persons with the object of providing some fresh air for poor children during the heated term, the temperature being much lower than in the city. There is no provision for keeping visitors over night, except in the little hospital, but a small steamer is owned by the Association, which plies back and forth all day long. From 1200 to 1400 persons can be accommodated every day. Last year 49,000 visitors were admitted. Some nourishing articles of food, sick diet, tea, etc., are provided for mothers and children, while toys and gymnastic apparatus afford them exercise. This sanitarium at a small expense is of inestimable benefit to the poor of the lower part of the city.

Correspondence.

LETTER FROM LONDON.

THE INTERNATIONAL HEALTH EXHIBITION.

LONDON, *May* 22, 1884.

MR. EDITOR, — The 'bus driver, with a bouquet in his button-hole, smilingly shouts to the stream of people pouring down the Strand, "*'ealth Exhibition, sir;*" the conductor says, as one passes up to amuse himself gazing at the human comedy from the top of his stage, "*Fine day, sir, for the four-in-'and meet, sir, at 'yde Park, sir, eleven o'clock, sir.*" John Bull instructing himself and John Bull amusing himself, both very serious matters, not to be treated lightly, and about which there must be no unnecessary waste of time or nonsense.

The horses were magnificent. A crowd is always interesting. The riding was some good, some bad, some very bad. The faces and figures of the ladies driving and on horseback, much to our surprise, were not so suggestive of health and strength as the general appearance of the corresponding class on the Mill Dam and the Brighton road, although the opposite was true of the thousands on foot.

Ten thousand people visit the Health Exhibition daily, attracted partly by the promenades in the charming gardens, illuminated at night, by the bands of music, the playing of the great organ in the Albert Hall, and the very entertaining and instructive historical representations of early costumes and models of the houses of London of past centuries. It is more than a health exhibition. It is a great and amusing six-months' show, at which the populace can divert itself, and at the same time learn an immense deal with regard to the economies, the conveniences, the elegances, and, so far as health is concerned, the necessities of the school, the workshop, and the household. It has a room where useful lessons are given in cookery, and cheap dinners may be studied practically; but the "first-class restaurants" are, to use a favorite English expression, nasty, — a serious fault in the eyes of those people who think that all this talk about filth-diseases and cleanliness has some influence in diminishing death-rates, but an immense value as a civilizing agent. For popular instruction the whole affair is admirably arranged, but the student of sanitary science will not find enough to repay him for the sacrifice of much time in getting there, except in so far as he is interested in the devices of the various manufacturers and shopkeepers for applying sanitary principles to the daily uses of life, all of which is to be learned chiefly from the exhibitions and advertisements of their wares by some sixteen hundred business firms, some of whom announce to the nobility and gentry the great things that they can do if you give them a chance. At lunch our eyes rest upon walls covered with convenient advice to go to Peter Robinson's for the newest fashions, with enticements to drink non-alcoholic, sparkling morella, a substitute for wine, or zoedone at lemonade prices, until we see that *The Lancet* has analyzed Camuset's champagne, and gives it unqualified praise, but we look in vain for the wonders that Eno's fruit salts can perform.

In the food department there are raw materials and machinery in motion to show the various processes of making them eatable; preserved provisions of all kinds; the processes of the dairy, from the gentle cow in the stall to the pretty dairy-maid patting the butter; every sort of drink, alcoholic and otherwise; diets for invalids and infants; methods of cooking, including bakeries, and the possible dangers to health from their mismanagement; adulterations; parasites found in meat; methods of preserving food; tobacco.

The relative values of different articles of dress, especially of underclothing, as to the various requirements of health and comfort, in different climates, and for all sorts of purposes; the effects of poisonous dyes, the costumes suitable for female operatives, for different trades and workshops, for nurses, soldiers, sailors, firemen; illustrations of badly-shaped boots, and spinal and thoracic deformities from tight lacing; the processes of manufacture of clothing, — all are admirably shown; but it is safe to say that the latest fashion of the returning narrow corsets in the displays from Regent Street will make more impression on the average young woman than the pictures of the squeezed livers.

Among the other departments the most important are water supply and drainage of the dwelling-house, illustrated admirably to the least detail, and especially with two dwellings, one to show bad and the other good sanitary arrangements; construction and fittings of the dwelling-house, including fabrics for such use, wall papers free from arsenic, etc.; heating, lighting,

ventilating, and smoke abatement in dwellings, very fully treated; school hygiene, desks, and methods of instruction; ambulance equipments; workshops; the meteorology of health; demonstration in the laboratory of methods of examining food, air, water, soil, constructive materials of houses, disinfectants, etc.

There are to be conferences in the leading scientific societies, open to the visitors to the exhibition, on the subjects of dwellings for the poor; domestic sanitation in the urban and rural districts; industrial diseases; how infectious diseases are spread; notification of infectious diseases; disposal of the dead, cremation; meat supply; water supply and distribution; construction of houses with regard to sanitary arrangements; oral instruction of the deaf and dumb; electric lighting, municipal and domestic, or on other subjects connected with application of electrical science; food adulteration and analysis; sanitary legislation; some subject cognate to the work of the Society; the effect on the health of teachers and children of overwork in schools; ambulance work in peace and war; bee-keeping; tropical sanitation. Shilling handbooks are on sale throughout the exhibition by competent, many of them by eminent, writers on Healthy Villages, illustrated. Healthy Bed-Rooms and Nurseries, including the Lying-in Room. Healthy and Unhealthy Houses in Town and Country, illustrated. Healthy Furniture and Decoration, illustrated. Healthy Schools. Health in Workshops, illustrated. Manual of Heating, Lighting, and Ventilation, illustrated. Food. Principles of Cookery. Food and Cookery for Infants and Invalids. Alcoholic Drinks. Water and Unfermented Beverages. Fruits of all Countries, illustrated. Salt and other Condiments. Legal Obligations in respect to Dwellings of the Poor. "Our Duty," or Moral Responsibility of the Individual in regard to Health. Laboratory Guide to Public Health Investigation, illustrated. Physiology of Digestion and the Digestive Organs, illustrated. Fermentation. Spread of Infection. Scavengering and other such Work in Large Cities, illustrated. London Water Supply. Fires and Fire Brigades, illustrated. Athletics, Part I., illustrated. Athletics, Part II. Dress in relation to Health and Climate, illustrated. Accidental Injuries, their Prevention and First Management, illustrated. The Ambulance, illustrated. The Influence of Schools of Art on Manufacturing Industry. * * *

"THE 'TAXATION' THEORY OF EXPERT TESTIMONY."

Boston, *June* 9, 1884.

Mr. Editor, — Having read with great pleasure the article in your journal of June 5th on The "Taxation" Theory of Expert Testimony, I am tempted to express the opinion that not only is it, as you say, a greater injustice to call upon experts upon the same terms as are jurymen, and that they should rather be considered as officers of the court as are judges and sheriffs; but I would go farther, and maintain that the only excuse for not treating jurymen in the same way is the assumption that it is impracticable; in short, that it is a very high-handed act to force any man to serve the State in any capacity whatever in opposition to his own interests or wishes. Such an act may be excusable when our limited knowledge shows us no alternative; but while this consideration may, perhaps, be an excuse for conscription or for the drawing of juries, yet imperfections of civilization ought not to be pleaded when they do not exist, and there is certainly no necessity for compelling the services of experts. If there were, the least that could be done in honor would be payment for services at the market value. For my own part I can see no other ground that is not simply communism. Very truly yours, E. M. B.

RETAINED PLACENTA OF ABORTION, WITH HÆMORRHAGE.

Brighton, *June* 5, 1884.

Mr. Editor, — The practice which has been successful and satisfactory in the abortion cases that have fallen into my hands for the last fifteen years is, first, to stop the hæmorrhage, which is the one alarming symptom in nine cases out of ten which occasions the calling of the physician; and the most certain, sure, and effective way of doing this is to remove at once the placenta manually. If this is done the hæmorrhage ceases, the danger from septicæmia is practically nil, and, until this is done, "the anxious days,' and nights too, are a certainty; frightful hæmorrhages may, and in a certain per cent. of cases do, occur. In other cases the placenta is retained from inability of the uterus to throw it off, and putrefaction commences with its attendant danger of septicæmia. Many cases left to nature come out all right of themselves; but these last are not those that come under the observation of the physician.

Early in my practice I concluded, when an abortion was so far in progress that the fœtus had escaped, that the safest, most satisfactory, and common sense practice was to complete the abortion as quickly as possible. The deaths from abortion are mostly from effects of hæmorrhage and septicæmia. Any delay, therefore, in the removal of the placenta make "the anxious days" certain to come, provoke the occasion of hæmorrhage, and the possibility of attacks of septicæmia. With the complete removal of the secundines all apprehension from hæmorrhage and septicæmia is at an end.

In the treatment of disease if the cause is removed the disease is often soon cured. In abortion the hæmorrhage is due to the retained placenta. Septicæmia after abortion is caused by the retained placenta, or a portion of it. The most scientific treatment, then, of retained placenta after abortion, with resulting hæmorrhage or septicæmia, would seem to be its immediate removal, and in my experience the fingers are the best and only instruments needed. Any other method of treatment is but temporizing; plugging the vagina, by Dr. Lawson Tait, has been styled "barbarous and unscientific." Immediate removal of the placenta is but carrying out the perfect method of nature, which makes the effort in nearly all cases to remove it, and succeeds in most, but in certain of the cases to which physicians are called she fails from lack of expulsive force in the uterus. By her efforts, however, the uterus from being high up is forced down lower in the pelvis, is more easily reached, the os is made softer, more dilatable, and, with the left hand above the pubes, the forefinger of the right hand can be made to reach and remove the placenta in all cases.

Having practiced medicine in a town for seven years, near a successful abortionist, I presume it has

been my lot to see more cases of hæmorrhage and septicæmia after abortion has been procured than usually falls to the lot of the general practitioner; unwittingly I contributed to his success by saving the lives of patients that came into my hands *in extremis*. The conclusions and deductions as above are the result of my experience.

Yours etc., MARSHALL L. BROWN, M. D.

Miscellany.

EFFECTS OF POLITICAL EVENTS ON THE FORMS OF INSANITY.

THE *Medical Times and Gazette* (May 3d) thus summarizes the introductory lecture of Dr. Legrand du Saulle (reported in No. 13 of *Progrès Médical*) at the Salpetrière this year, in which he pointed out that war and rioting only induce insanity in the predisposed. There was no increase in the number of the insane during the troubles that prevailed from 1847 to 1854, and it was the same during the events of 1870 and 1871. In his opinion, speculation, the thirst for gold, and sudden changes in fortune are the chief causes that provoke insanity. The constantly increasing resources of the Assistance Médicale, by enabling it to aid so large a number of patients, have materially influenced the statistics of mental diseases — for formerly a large number of epileptics, imbeciles, and persons suffering from senile dementia, who would have remained unnoticed in the rural districts, are now inmates of asylums. If the events of 1870–1871 have exerted any decided effect on the mental condition of the Parisian population, it is because they modified the conditions of existence. Thus, on the declaration of war, when a considerable number of young persons joined the colors, numerous cases of subacute alcoholism were met with among quite young people, as a consequence of the excesses committed under the influence of the emotion caused by the approaching departure. When the enemy approached, and investment was menaced, the population of the suburbs took refuge in Paris, and these unfortunate beings, in a state of constant anxiety and anguish, insufficiently aided and badly fed, furnished a good many cases of melancholic insanity. Other disturbances arose under the conditions of existence necessitated by the defense. The men passing their time at the fortifications and committing excesses in drink were in large numbers attacked with subacute alcoholism, while the ill-fed women presented the psychical disturbances due to inanition — hallucinations, melancholic delirium, etc. Still, insanity, properly so-called, seemed to have decreased. At the time of the bombardment, the inhabitants of Montrouge took refuge in the other districts, and a great many became subjects of panophobia or "perplexed melancholia," several of the women presenting, without any period of invasion, the phenomena of melancholia with stupor or stupidity. During all this period the epileptics in the Salpetrière underwent no increase in the number of their attacks. One single category of the insane exhibited a notable increase, namely, the *inventors*, who still continued numerous until the period of the Commune. In conformity with the documents on the hereditary and personal antecedents of the subjects of psychical disturbances during this period the existence of obsidional insanity cannot be admitted.

The pathogenic influence of the events of the siege was not only felt among adults, but was also very marked on the development of infants conceived at this epoch. The numerous disturbances in their evolution observed among infants born in the later months of 1871, and the exceptional mortality which occurred amongst them, caused them to be designated by the working population as *les enfants du siège* — a name synonymous with an ill-formed infant destined to a fatal lot. Among ninety-two infants conceived during the siege, Dr. Legrand du Saulle found that in sixty-four there were physical, intellectual, or moral anomalies, the remaining twenty-eight being in general small and sickly. As to the pathogenic influence under which these anomalies are developed, that must be a complex one, the principal elements of which are alcoholism, inanition, and the psychical condition determined by the moral shock under circumstances so eminently dramatic.

INSTITUTION FOR FEEBLE-MINDED CHILDREN IN PENNSYLVANIA.

AT a meeting of the Board of Directors of the Pennsylvania Institution for Feeble-Minded Children, held lately at Elwyn, the condition of the feeble-minded children of the State was discussed. The census of 1880 reports the feeble-minded population of Pennsylvania to be 6503. Of this number 2323 are under eighteen years of age. The correspondence of the institution establishes the fact that at least 1500 feeble-minded children are in the homes of persons too poor to pay for their support in any institution, and yet too much attached to their unfortunate offspring to place them in county almshouses. The injury to the community from the presence of this element is such that those who examine this problem believe it would be wise economy to isolate the feeble-minded and idiotic, and establish in Delaware County, in connection with the present institution, an asylum village, to consist of farm-houses for those who are able to work, a hospital home for the helpless, and a central educational department. The institution already embraces these features, and by utilizing its farm lands the cost of maintenance has so diminished that it is now believed a plan embracing all this dependent population of the State is feasible.

ANOTHER PREHISTORIC HUMAN SKELETON.

IN *Science* (May 2, 1884) we find figures illustrating the skull from a skeleton which was found about a month ago in one of the grottoes at Mentone, France (next to the one in which a skeleton was found some twelve years ago by Rivière). The description was forwarded by Mr. Wilson, the United States consul at Nice, under date of March 31st. The skeleton was found in a cavern at a depth of eight and a half metres, under well-defined strata; one a metre and a half thick composed of cinders, ashes, burnt earth, and charcoal. More or less worked flint chips were found with it comparing well with those found with Rivière's skeleton.

The skeleton was complete; but, as the result of a quarrel over the ownership, the body was stolen, and its whereabouts are still unknown. The skull was broken in the exhumation, but is nearly perfect; and, when found, a large chip flint was found resting against

the top of the head, and two others resting like epaulets against the shoulders. The length of the skull, from the back of the head to the forehead, was eighteen centimetres, and from the back of the head to the projecting eyebrows, nineteen centimetres and a half; the breadth was fourteen centimetres. One femur was saved from loss, and measured forty-nine centimetres in length.

REPORTED MORTALITY FOR THE WEEK ENDING MAY 31, 1884.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from				
				The Principal Infectious Diseases.	Consumption.	Diarrhœal Diseases.	Diphtheria and Croup.	Measles.

Deaths reported 2205 (no reports from Brooklyn, Buffalo, and Providence): under five years of age, 917; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 467, consumption 337, lung diseases 230, diphtheria and croup 101, diarrhœal diseases 90, measles 68, scarlet fever 67, typhoid fever 36, whooping-cough 31, cerebro-spinal meningitis 22, malarial fevers 22, erysipelas 11, puerperal fever 10, small-pox nine. From *scarlet fever*, Philadelphia 22, Chicago 13, New York 11, Boston six, St. Louis and District of Columbia four each, Baltimore two, Cincinnati, Pittsburg, Milwaukee, New Haven, and Worcester one each. From *typhoid fever*, Philadelphia 14, New York six, Chicago four, Boston three, New Orleans, and Holyoke two each, Baltimore, District of Columbia, Pittsburg, Milwaukee, and Nashville one each. From *whooping-cough*, New York 14, Boston five, Philadelphia three, Baltimore New Orleans, and Pittsburg two each, Chicago, St. Louis, and Somerville one each. From *cerebro-spinal meningitis*, New York four, Chicago five, Philadelphia three, Baltimore and Lawrence two each, St. Louis, Cincinnati, Milwaukee, Somerville, Stoneham, and Leicester one each. From *malarial fevers*, New Orleans 10, New York seven, Chicago and St. Louis two each, Baltimore one. From *erysipelas*, New York seven, Philadelphia two, Chicago and Cincinnati one each. From *puerperal fever*, Chicago and Boston two each, New York, Baltimore, District of Columbia, Milwaukee, Lowell, and Westford one each. From *small-pox*, New Orleans seven, Philadelphia and Cincinnati one each.

In 100 cities and towns of Massachusetts, with an estimated population of 1,378,000 (estimated population of the State 1,955,104), the total death-rate for the week was 16.50 against 14.86 and 15.88 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending May 17th, the death-rate was 21.1. Deaths reported 3540: acute diseases of the respiratory organs (London) 295, whooping-cough 182, measles 151, scarlet fever 70, small-pox (London 30, Liverpool five, Sheffield and Hull three each, Sunderland and Newcastle one each) 43, fever 35, diarrhœa 35, diphtheria 23. The death-rates ranged from 16.2 in Brighton to 27.5 in Manchester; Sunderland 16.5; Bristol 18.6; Sheffield 18.9; Birkenhead 18.9; Leicester 19.6; London 19.9; Blackburn 20.3; Bradford 22.7; Birmingham 22.8; Liverpool 24.3; Leeds 25.5. In Edinburgh 24.7; Glasgow 27.6; Dublin 25.7.

For the week ending May 17th, in the Swiss towns, there were 34 deaths from consumption, typhoid fever 31, lung diseases 19, diarrhœal diseases 16, diphtheria and croup two, measles one, scarlet fever one, whooping-cough one, erysipelas one. The death-rates were, at Geneva 11.2; Zurich 23.6; Basle 17.8; Berne 32.2.

The meteorological record for the week ending May 31st, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM MAY 31, 1884, TO JUNE 6, 1884.

MOORE, JOHN, lieutenant-colonel and assistant medical purveyor. Ordered to perform, in addition to his present duties, those of medical storekeeper, San Francisco, Cal.

JOHNSON, HENRY, captain and medical storekeeper. Relieved from duty at the medical purveying depot at San Francisco, Cal., and ordered to report for duty at the medical purveying depot, New York City, relieving Captain Andrew V. Cherbonnier, medical storekeeper.

CAPTAIN CHERBONNIER, on being relieved by Captain Johnson, will proceed to St. Louis, Mo., and report in person to Captain George T. Beall, medical storekeeper, and acting assistant medical purveyor, for duty at the purveying depot at St. Louis, relieving Captain Beall of his duties as medical storekeeper.

Paragraph 9, S. O. 128, A. G. O., June 3, 1884.

FRYER, BLENCOWE E., major and surgeon. Granted leave of absence for one year from July 1, 1884. Paragraph 7, S. O. 128, A. G. O., June 3, 1884.

HALL, JOHN D., captain and assistant surgeon. Granted leave of absence for three months, to take effect on his arrival at St. Paul, Minn. Paragraph 8, S. O. 128, A. G. O., June 3, 1884.

HEGER, ANTHONY, major and surgeon. Assigned to duty at Fort McHenry, Md., as post surgeon. Paragraph 1, S. O. 108, headquarters Department of the East, June 2, 1884.

BAILY, JOS. C., major and surgeon. Now on leave of absence, is relieved from duty in Department of Texas, and ordered to report to commanding general, Department of the East, for assignment to duty at Fort Monroe, Va., to relieve Lieut.-Col. Charles Page, surgeon U. S. Army, on July 1, 1884, from duty at that station.

LIEUT.-COL. PAGE, on being relieved by Major Baily, will proceed to Fort Leavenworth, Kans., and report to commanding general, Department of the Missouri, for assignment to duty as medical director of that department.

Paragraph 12, S. O. 125, A. G. O., May 29, 1884.

WRIGHT, J. P., major and surgeon. Directed to perform, temporarily, in addition to his other duties, those of medical director, Department of the Missouri. Paragraph 2, S. O. 107, headquarters Department of Missouri, May 28, 1884.

HUNTINGTON, DAVID L., major and surgeon. During the absence of the Surgeon-General directed to take charge of the office of the Surgeon-General and perform his duties. Paragraph 6, S. O. 129, A. G. O., June 4, 1884.

BENTLEY, EDWIN, major and surgeon. Assigned to duty at Fort Clark, Texas, as post surgeon. Paragraph 1, S. O. 68, headquarters Department of Texas, May 31, 1884.

KOERPER, EGON A., captain and assistant surgeon. Assigned to duty at Fort Keogh, M. T. Paragraph 1, S. O. 58, headquarters Department of Dakota, May 27, 1884.

BARNETT, RICHARDS, captain and assistant surgeon. Now on sick leave of absence, is relieved from duty at Columbus Barracks, Ohio, and ordered to report to commanding general, Department of the East, for assignment to duty. Paragraph 2, S. O. 129, A. G. O., June 4, 1884.

MIDDLETON, PASSMORE, captain and assistant surgeon. Granted leave of absence for one month on surgeon's certificate of disability. Paragraph 2, S. O. 107, headquarters Department of Missouri, May 28, 1884.

WILSON, GEORGE F., first lieutenant and assistant surgeon. Relieved from temporary duty at Fort Canby, Washington Territory, and ordered to return to his proper station (Fort Walla Walla, Washington Territory). Paragraph 2, S. O. 70, headquarters Department of Columbia, May 26, 1884.

OWEN, WILLIAM O., JR., first lieutenant and assistant surgeon. Having reported at these headquarters, in compliance with paragraph 5, Department Special Orders, No. 62, current series, will return to, and take station at, Fort Stevens, Oregon.

In addition to his duties at Fort Stevens, Assistant Surgeon Owen will perform those of medical officer at Fort Canby, Washington Territory. Paragraph 1, S. O. 70, headquarterss Department of Columbia, May 26, 1884.

LIST OF OFFICIAL CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING JUNE 7, 1884.

MURRAY, T. M., passed assistant surgeon, detached from U. S. S. Passaic, ordered to U. S. S. Constellation.

MARTIN, W., assistant surgeon, detached from U. S. S. Constellation, ordered to U. S. S. Passaic.

CRAIG, T. C., passed assistant surgeon, detached from U. S. S. Minnesota, ordered to U. S. S. Vandalia.

DEANE, C. W., passed assistant surgeon, detached from U. S. S. Vandalia, ordered to U. S. S. Minnesota.

HALL, T. H., passed assistant surgeon, detached from U. S. S. Minnesota, ordered to Naval Hospital, Brooklyn.

WALES, P. S., medical director, to continue present duty until August 1, 1884.

WELLS, H. M., surgeon, to temporary duty at Naval Laboratory.

MARSTELLER, E. H., passed assistant surgeon, detached from U. S. S. Vermont, ordered to U. S. S. Monongahela.

SCOTT, H. B, assistant surgeon, commission to date from July 11, 1883.

MEANS, V. C. B., assistant surgeon, commission to date from June 3, 1884.

HESLER, F. A., assistant surgeon, commission to date from June 3, 1884.

RHODE ISLAND MEDICAL SOCIETY. — The seventy-third Annual Meeting of the Rhode Island Medical Society will be held at ten o'clock A. M., Thursday, June 19, 1884, in Lyceum Hall, 62 Westminster Street, Providence. The Annual Address will be delivered by George I. Chace, LL. D., at one o'clock, P. M. Tickets to the Annual Dinner, which will be served at the Narragansett Hotel, can be obtained of the Treasurer, Dr. C. H. Leonard. The Board of Censors will meet in the Medical Library, 54 North Main Street, Providence, at ten o'clock, A. M., on Tuesday, June 17th, and in Lyceum Hall on the morning of the Annual Meeting.

GEORGE D. HERSEY, *Recording Secretary.*

SEWAGE SYSTEMS AND THE EPURATION OF SEWAGE BY IRRIGATION AND AGRICULTURE.[1]

BY HENRY J. BARNES, M. D.

MANY of the cities and towns of Massachusetts, as well as those throughout the country, have in the near future this question to dispose of in a scientific and practical manner. Political economy and the public health demand already in many communities attention to this subject. An epidemic of typhoid fever in a neighboring town would be a very dangerous menace to the health of the citizens of Boston in consequence of the water supply of the latter being the receptacle for the drainage and dejections of the inhabitants of the former. A beautiful lake in the vicinity of Boston is made so filthy by a large sewer discharging in it, that twice a public cry of reprobation has been raised against it. The valley of one of our large rivers has been rendered almost uninhabitable by the drainage of a large inland city. It is now said that the citizens of Chicago are much of the time drinking their own sewage as a result of taking water from a lake with which their sewerage system connects, and we may add that the city which is not troubled by its system of drainage is the exception and not the rule.

The effects of pollution by sewage of wells, springs, rivers, and ponds used for domestic purposes, are so generally recognized that no attempt is made to collate the many, many calamities which have befallen cities, towns, villages, and families through ignorance or indifference as to what disposition is made of the refuse matter of dwellings, and we must also acknowledge that a comprehensive system of disposing of sewage must be inaugurated in the near future, both in towns and by every individual hamlet. The present methods of gathering in cess-pools or subterranean channels, which discharge in a manner to jeopardize health and comfort of ourselves and neighbors, must be abandoned for a system which shall dispose of and purify the sewage in a practical manner, or we must give up some of our large rivers for sewerage systems, or construct at enormous expense metropolitan systems, both of which have proved unsatisfactory or failures in Europe.

London's metropolitan system, which discharges in the maritime Thames about twenty-one miles below the city, of which so much was expected, and cited as an example Boston might imitate, has proved far from what was anticipated. The sewage instead of going to sea, or being diluted to an extent which would render it innoxious, is deposited by the tides above and below the mouth of the sewer in such a quantity as to cause a great cry of indignation from the inhabitants living along the banks of the river, and numerous petitions to Parliament asking for relief have been presented.

Torquay and Brighton draining directly into the sea have experienced similar results, and their systems are pronounced failures. The once beautiful bay of Naples is to-day a reeking pool of filth. A recitation of the many examples of pollution of rivers both in Europe and America, and the attendant evil, is unnecessary, but the following list of English cities where the courts have enjoined drainage in rivers suggest what we may anticipate in this country; Banbury, Blackburn, Chorley, Doncaster, Harrowgate, Leamington, Merthyr-Tydfil, Rugby, Tunbridge Wells, Warwick, Kendal, Birmingham, Bolton le Moors, Bradford, Coventry, Leeds, Halifax, and Rochdale.

In 1870 the Royal Commissioners reporting on the pollution of the Mersey and the Ribble stated that "sewage discharged in running water is not materially changed for many hours by oxidation." This they demonstrated by the following experiment: A volume of filtered sewage from a drain of London was mixed with nine parts of pure water. Analysis of this mixture showed it to contain per 100,000 parts 267 parts of carbonaceous matter and .81 parts of nitrogenous matter. It was exposed each day to light and air, shaken and drawn by small siphons in a manner to cause a fall of over three feet from vessel to vessel. At the end of 96 hours there remained 250 parts of carbonaceous matter and .58 parts of nitrogenous matter, indicating a loss of but 17 parts of carbonaceous matter and .23 parts of nitrogenous matter. At the end of 192 hours it had lost but 25 per cent. of carbonaceous matter and 33⅓ per cent. of nitrogenous matter. This experiment was made in a temperature of about 68° F., and designed to show the change likely to take place in the current of a river running at the rate of one mile per hour, and carrying ten per cent. of sewage. They concluded there was not a river in England long enough to dispose of a moderate amount of sewage through oxidation.

I. Babut du Maris says, "it has been proved that the water of rivers do not lose a material amount of azote nitrogen in a run of over three hundred miles. And the Prussian Government has consequently forbidden the pollution of rivers and sea-ports by the discharge of the detritus of cities.

The effects of imperfect sewerage systems are forcibly portrayed in a paper printed in the *Boston Medical and Surgical Journal* of February 22 and March 1, 1883. In that paper Dr. Morton Prince collates many epidemics of typhoid fever for this cause. He says, "it is estimated that in this State (Massachusetts) alone there are ten thousand cases of typhoid each year," and every one knows a large proportion may be fairly charged to defective drainage. How imperfect sewerage causes this disease was well illustrated at Nahant, Massachusetts, in 1881, and thoroughly reported by Mr. Ernest Bowditch. A paragraph from page 246 of the Supplementary Report of the State Board of Health 1882–83 would properly introduce the question discussed in this paper, as the successful epuration of sewage by irrigation and agriculture depends upon where, and to what extent, nature provides in the soil for the elimination of filth. Mr. Bowditch says, after noting the improvement in the sanitary condition of the town the year following the epidemic, "While the conclusions as to soil recovery may be derived from insufficient premises, perhaps calling attention to the subject may lead to the discovery of facts warranting systematic research in this direction that may be of great sanitary value." Dr. Frankland wrote in May, 1881: "There are in nature powerful agents for the destruction of disease. It cannot be doubted otherwise the human race would long ago have been exterminated. The problem is not entirely solved, but experience appears to demonstrate this action on sewage employed in irrigation; for when known to be infected by cholera and typhoid fever in England it has never

[1] Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Suffolk District Medical Society, April 30, 1884.

produced these diseases in the inhabitants living on the sewage farms and consuming the produce."

Many and varied are the systems adopted and methods employed with the object of disposing of sewage. Surface drainage, cess-pools, subterranean drainage, and the pneumatic system of Liemur, are employed for collecting and discharging in rivers, ponds, bays, oceans, and on the land are the most common means of distribution. Filtration, precipitation, the employment of chemical agents, irrigation, and agriculture are some of the measures adopted for this purpose of epuration.

CESS-POOLS.

Depositing sewage in cess-pools is one of the most common as well as antiquated methods employed. They are emptied at intervals varying from one week to five or more years. It involves the concentration of fermentescible matter and the consequent generation of gases dangerous to health, beside the vitiation of subsoil water. The soluble organic matter contained in them is capable of very long journeys under ground, with the loss of coloring matter only, as many analyses have proved. Their use should not be tolerated, except the walls are made impervious to liquids, and their being emptied at short intervals. A writer on the subject says: "The time is not far distant when they will be pronounced a relic of barbarism."

DOWNWARD INTERMITTENT FILTRATION PRACTICED AT KENDAL, ENGLAND.

The population is about 14,000. There are 450 water closets connected with the sewers, which discharge 868,000 gallons per day. A reservoir of deposit was first constructed, which overflowed on a farm of about fifteen acres, with the object of utilization by agriculture. The area of the farm proved insufficient to epurate the sewage completely, and five acres of filter beds were added. These, with the farm, suffice to purify the water. In 1875 the products of one third of the farm, consisting of cabbages, beets, celery, and rhubarb, sold for $500. Oats and rye on another third $375, and on the remaining five acres $225 worth of hay was raised, making a total of $1100 worth of produce from fifteen acres. The application of the sewage cost $550.

The operation of the same system constructed by I. Bailey Denton at Abingdon, Great Malvern, and Halstead, England, and at Forfar, Scotland, has proved satisfactory, inasmuch as sufficient matter is eliminated to allow the effluent discharge into neighboring rivers, although it contains a large amount of putrescible matter, as indicated by analyses. It just escapes the ban of the Pollution Act.

THE PNEUMATIC SYSTEM OF LIEMUR

is employed at Amsterdam for a limited number of the inhabitants. The sewer pipes are made of iron, with air-tight joints. An air-pump makes a vacuum. Closets are opened simultaneously once a day in section after section of the city; the contents are drawn to the mouth of the sewer, from which they are carried away in barrels and deposited on the land. Its enormous cost bars its employment where any other system can be used.

UPWARD FILTRATION AT BIRMINGHAM, ENGLAND.

Population about 350,000. Eight thousand water closets are connected with the sewers, which discharge about 14,000,000 gallons per day in the river Tame. An injunction was obtained to prevent the discharge in the river unless the sewage was first purified. A reservoir of deposit was built, and a system of upward filtration, but complaint of the continued pollution of the river necessitated its abandonment. The city then attempted irrigation and agriculture, but this was also enjoined. Finally, after much delay and litigation, the city bought 120 acres of land, and on the advice of an engineer constructed a new reservoir of deposit, where they treat the sewage with lime. To 13,434,860 gallons is added thirteen tons of lime each day. This clarifies the water to a certain extent by causing a deposit of about 300 tons per day, which is carted out and buried on the land.

It has been an easy matter to separate material in suspension from drain water by filtration, but as this represents only about one seventh part of the value of sewage for fertilizing purposes, the process, though simple, has never proved remunerative, and chemists have been employed to suggest agents which would precipitate the soluble matter, which represents six sevenths of the value. Lime has been employed at Tottenham, Blackburn, and Leicester, but the Royal Commissioners report of each a failure, inasmuch as the drain water after being thus treated contains a large amount of putrescible matter.

TREATMENT BY LIME AND CHLORIDE OF IRON AT NORTHAMPTON, ENGLAND.

To 250,000 gallons of sewage is added about 100 quarts of lime and six quarts of chloride of iron, which is thoroughly mixed, and afterwards passed by upward filtration through a layer of calcinated iron eight inches thick. The water comes out without color or odor, and is then allowed to flow into the river. At first there was no complaint, notwithstanding the presence of a large amount of putrescible matter, but later the river became offensive, and the court has enjoined the discharge there.

THE A. B. C. METHOD OF SILLAR.

A mixture consisting of six hundred parts of alum, twenty-five parts of burned clay, one part of blood, ten parts of salt, nineteen hundred parts of clay, fifteen parts of animal charcoal, five parts of magnesia, twenty parts of wood charcoal, ten parts of manganet of potash, two parts of calcined magnesia, is added to the sewage, to be treated in a proportion of about one pound of the mixture to 250 gallons, thoroughly agitated, and then allowed to settle in large reservoirs, which are alternately emptied, and the detritus taken out dried, and sold as a valuable fertilizer. The residuary water still contains putrescible matter, and notably more ammonia than the sewage before being treated.

PRECIPITATION BY CHEMICAL MEANS AT COVENTRY, ENGLAND.

Population 40,000. Five thousand water closets are connected with the sewers, which discharged 2,289,000 gallons of sewage in the river Sherburne. Complaint and litigation was the result. A reservoir of deposit was constructed, after which the sewage was allowed to filter across a gravel bed three feet thick. This proved unsatisfactory, as only solid matter was taken out, and the court again interfered with an injunction. A contract was then made with a fertilizer company, which agreed

to epurate the sewage for fourteen years at $3750 per year, the company engaging to erect building and machinery, and furnish the necessary tools. An extractor first separates the solid matter. The liquid is then run into caldrons under the first group of buildings. Agitators mix impure sulphate of alumine with it at a boiling temperature. It is then run into a second set of vessels, where milk of lime is added and thoroughly mixed, then discharged alternately into four reservoirs in the open air, which are cleaned every fourth day. The liquid thus treated comes out sufficiently pure, and is allowed to filter over about four acres, and finally find its way into the river. Thirty tons of detritus is taken each day from the reservoirs, piled to dry, and subsequently treated by artificial heat. The works are not in operation at night, except the discharge of sewage on the filter beds. Twenty-two tons of coal, one ton of sulphuric acid, nine tons of sulphate of alumine, and four tons of lime are used each week. The company's net loss is about $7500 each year.

After long and costly experiments the greatest chemists have declared that in practice the only manner to epurate sewage is to send it on the land, which eliminates the polluting elements and fertilizing matter for the good of vegetation and the soil. Dr. Angus Smith says: "In all cases the best results are obtained by irrigation." And Dr. Carpenter certifies, in a notice read at the International Congress in 1881, "the only way ammonia could be eliminated from sewage is by irrigation."

A commission appointed by Parliament, composed of Messrs. Dennison, Frankland, and Morton, reported: "The actual resources of chemistry do not permit the hope that the polluting matter dissolved in sewage can be precipitated and sent away by any appliance of chemical reaction, and unless new chemical laws are discovered it is useless to attempt the employment of chemical agents. Epuration must be confided to Dame Nature."

"Millions of dollars have been expended in France in chemical experiments on sewage, all of which have been condemned." *I. Babut du Maris.*

At the Women's Prison in Sherborn, Massachusetts, epuration of sewage is attempted by what is known as Colonel Waring's method. Five acres of land are here employed in the water-shed of Lake Cochituate about two miles from the lake, with which it is connected by a brook, one of the tributaries of Boston's water supply. The sewage is distributed over the land by tile with broken joints laid fourteen inches below the surface, five feet apart. The effluent drainage is provided for by cross sections of tile laid five feet under ground, which, after collecting the water, discharge in the brook. This system is said by the prison authorities to work satisfactorily. "The water coming from the ground is as clear as spring water, and was selected by an expert as such on inspection." This only indicates clarification, and we regret that analyses made were not published, as no one seems to know where they are at the present time. There can be no doubt but the grass, which is the vegetation on the land, takes nourishment from the sewage, for the lines of drain are clearly marked by a better growth directly over them which does not extend to the intervals between. One of the defects of this system has already been experienced. Insoluble matter has filled the interstices between the tile, and prevented fluids from passing through, necessitating their being taken up and relaid. At a depth of fourteen inches the influence of vegetation and the infusoria must be lost on much of the sewage, which was probably disclosed by the analyses, rendering it desirable they should be pigeon-holed. Since writing the preceding, a visit to the prison more than confirms the anticipated objection to the system, and the following analyses, obtained in the office of the State Board of Health, are proof beyond dispute that the system amounts to nothing by way of purifying the sewage; and that the lake is practically a mammoth cesspool, the contents of which the citizens of Boston must drink: —

WOMEN'S PRISON SYSTEM. PARTS PER 100,000.

	Ammo.	Alb. Ammo.	Chlo.	Residue.
Supply End.	.240	.018	9.58	68.5
Flow End.	.232	.034	9.22	69.0

The exclusion of air from the sewage of this system keeps it fresh, the nitrogen is in an organic state, and consequently of no use to vegetation. A fertilizer should become ammoniacal by decomposition before it is capable of assimilation by plants. Analyses of sewage in Europe reveal the fact that there is no loss of fertilizing material in a closed conduit having a run of seven and one half miles. And examinations of the soil of sewage farms show that in all instances the sand one foot below the surface is as pure and white as that where irrigation is not practiced.

In the Mystic Valley the sewage of tanneries has for several years been pumped by the city of Boston into small reservoirs of deposit obviously too small to eliminate even the matter in suspension. From the tank there is an overflow into a shallow ditch several hundred feet long, in which are set several brush dams, after which it discharges into Mystic lower basin. The result of this treatment is to start putrefaction by warmth and free exposure to air, and thus produce a stench which people living in the vicinity claim has greatly reduced the value of real estate. It does not merit extended description as the efforts thus far made merely amount to a flirtation with the subject.

A few of the farmers living along the Blackstone River are beginning to appreciate the valuable fertilizing material conveyed by the current from Worcester, Mass. One farmer states that his meadow lands which were practically abandoned, it not paying to harvest the grass, now produce crops which add several hundred dollars a year to the value of his farm. Others are placing obstructions in the river with the object of turning the water on the land.

During the past ten years sanitarians and engineers have made great progress towards a solution of this question, and it is fair to presume, from the great increase in the number of cities and towns that have adopted irrigation and agriculture as the means of purifying sewage, that this method has proved the most satisfactory. Berlin has two large farms devoted to this object, one of 2035 acres and another of 1818 acres. A great many chemical experiments were tried before the adoption of the present system. They proved very expensive, and none purified the water, although many clarified it. Finally, after experimenting in irrigation and agriculture for eighteen months on a little field of about three hectares (less than seven and one half acres), such favorable results were real-

ized that this system was adopted for the city, — the eminent Virchow working heartily in its favor. At the present time 1067 acres suffice to purify 15,060,000 gallons per day, the drainage of four fifths of the city, containing a population of over 600,000. There is some odor at the opening of the large sewer, but in the fields there is no smell, and the sanitary condition is all that could be desired. There never has been any complaint from the numerous adjoining habitations, and the effluent drain water of the farms is pure and clear, it being impossible to recognize by microscopy or chemistry any influences of the sewage. Vegetables and fruit trees grow luxuriantly on the land, and their roots make a perfect filter. Thirteen and one quarter tons of hay has been cut per hectare (a little less than two and one half acres).

(To be concluded.)

CASE IN PRACTICE. CHRONIC PLEURITIS WITH EXCESSIVE SANGUINOLENT EFFUSION.[1]

BY CHARLES R. CRANDALL, M. D., PORTLAND, MAINE.

MRS. S., aged fifty-eight, of large stature and scrofulous temperament, always had good health until the present illness. When I was first called to see her, which was several weeks prior to the attack now referred to, she complained of difficulty with her breathing accompanied by a cough. Making physical examination of the organs of the thorax I found a localized bronchitis in the posterior lobe of the left lung, in the region of the lower part of the scapula. I noted also that she showed symptoms of marked prostration, and that her digestion was impaired. She was benefited by the treatment instituted, and soon after passed from observation.

In about three weeks I was again summoned, and was informed that she had never fully recovered her strength, although she had followed a course of tonic treatment which I had suggested. She was perceptibly weaker than when I first saw her, and her daughter complained that she was restless, irritable, wakeful, and suffered some from pain apparently due to flatulence. Despite supporting treatment and medication as indicated, she steadily declined in general health for a week or so longer. Finally her daughter informed me that at times her mother seemed a little short of breath, and especially so at night and during the day when she changed her position from the bed to her chair in an adjoining room. Again making a thorough examination I found the kidneys to be normal, but that the quantity of urine was scanty. The liver was also normal so far as could be ascertained. The heart was in a healthy state, but its action was feeble and slightly irregular. The left lung remained in good condition, although the respiratory murmurs were abnormally distinct and percussion resonance intensified. Upon examining the right lung a wonderful revelation was met in the form of an excessive pleuritic effusion, which evidently nearly filled the entire pleural cavity. On auscultation the respiratory murmur was nearly absent in every part of the lung, save some bronchial respiration in the upper portion. On percussion, with the patient in a sitting posture, dullness and flatness were elicited all over the posterior, lateral, and anterior surfaces of the right lung, excepting a small area on the anterior surface above the mammary gland. Vocal fremitus was greatly diminished. The chest was dilated over an inch, but the condition of the intercostal spaces could not be inspected owing to the presence of a thick layer of fat. But the most remarkable feature regarding the excessive effusion thus discovered was the fact of its rapid accumulation without one solitary symptom of chill, fever, pain, or distress calculated to call the attention of either the patient or the physician to the process taking place. The only symptom of a nature to attract attention to the chest at all was some difficulty in breathing, but this was so slight that it resembled the disturbance often noticed in cases of debility, and accompanied by a moderate degree of heart failure.

On the same day that I made the above diagnosis I performed the operation of thoracentesis, assisted by Dr. S. H. Weeks, and removed one hundred and fifty ounces (or over four quarts and a half) of fluid, the color of which was about the shade of a dark, thick port wine. The patient bore the operation without any untoward symptoms, and as the fluid escaped confessed to feeling a sense of relief. Air immediately refilled the entire lung, causing a little pain and slight cough. The respiratory murmur soon became quite normal, while the percussion note was greatly improved.

The fluid proved to be highly albuminous, and when tested by heat it so solidified in the test tube that it had to be broken up to favor removal. Examining the effused fluid under the microscope it was found to contain an abundance of fresh, red blood corpuscles, many of which arranged themselves in rows like rouleaux of coin, while others existed separately, and were shrunken and contracted into angular and star-like shapes. There were also numerous leucocytes having normal characteristics, and a few endothelial cells. Pus was not present, nor were there any indications of an attempt towards organization. The specific gravity was 1022.

REMARKS.

Two months have now passed since I performed thoracentesis upon this patient, and the results have been most gratifying. Effusion recurred slowly to a moderate extent, not sufficient, however, to justify a repetition of the operation. The condition of the lung has remained good, and the general health of the patient has steadily improved. For several weeks she has been dressed and about her house, and of late has done a little work, and gone out of doors.

The foregoing case affords many points of practical clinical interest, but I will avoid trespassing upon the valuable time of the meeting longer than to touch upon a few of the most important.

(1.) It illustrates the inestimable value of thorough investigation. This patient did not have a single sign or symptom well calculated to call attention to the diseased pleura. There had not been any pain, chills, fever, sweats, lividity, or acceleration of pulse. True she had been annoyed by slight failure of breathing upon exertion, but no more than we often see in debilitated patients whose respiration and circulation are practically normal. When I informed her that there was a collection of water in her pleural cavity she ridiculed the idea. Had I taken her word regarding the condition of her thorax, I should have been misled

[1] Read before the Portland Medical Club, April 24, 1884.

in a woful manner. The condition verified the observation of Flint, that chronic pleuritis is often developed imperceptibly, and that it is likely to be overlooked by those who do not employ the physical methods of examination.

(2.) The diagnosis of uncomplicated latent or chronic pleural effusion is easily made when it exists to any extent. The history of the case often aids materially, and especially so if it discloses difficult breathing, insufficiency of breath, a dry, hacking cough, and ill-defined pain or uneasiness in the lower lateral portion of the thorax. Now if to this be added a high-pitched percussion note at the apex of the lung with decided dullness or flatness at the base, feeble, or inaudible vesicular murmur over the portion of the lung, where dullness is most marked, decreased vocal fremitus where the effusion is greatest, and increased percussion resonance on the healthy side, accompanied by a marked accentuated vesicular murmur, a group of ordinary signs and symptoms are met with which are characteristic and unmistakable. Hydrothorax is to be excluded by the absence of cardiac and renal disease, and by the fact that the accumulation is unilateral instead of bilateral; but if doubt exists the introduction of a large-sized hypodermic-syringe needle, or one of the small aspiratory needles, will quickly clear up any obscurity. Exploratory punctures are easily made, and are of great service, for they aid in diagnosticating, convince both the physician and the patient, and display the character of the fluid if any be present.

(3.) Another practical point is that diagnosis should be made early, for the presence of a pleural effusion of any extent is always prejudicial. It deprives the patient of the necessary amount of oxygen, burdens the heart by interfering with the pulmonary circulation, and impairs digestion and nutrition by inducing secondary congestion of the liver and stomach. Moreover, the longer an excess of effusion remains in the pleural cavity the greater the danger of its undergoing degenerative changes and giving rise to empyema. Prognosis is rendered much more favorable by an early detection of the effusion, and a correspondingly prompt treatment. It is the neglected cases which more often give rise to malnutrition and tuberculosis.

(4.) Again this case displays in an impressive manner the great value of thoracentesis or paracentesis as a therapeutical agent. Here was a condition where, in all probability, ordinary absorbent and alterative remedies would have been powerless, owing to the enormous quantity of fluid present, or had they by chance afforded relief it would at best have been a long and wearisome process. On the contrary, this valuable method at once reëstablished normal respiration, and also favored circulation and general nutrition to an extent which soon became very evident. In addition to prompt relief, it promoted the action of remedies to such a degree that permanent improvement rapidly ensued, and reaccumulation was largely prevented.

(5.) In regard to the extreme bloody color of the effusion, it was, to say the least, very suspicious and suggestive. As it began to flow, the first thought was that the aspirator needle had punctured a large blood-vessel or else had wounded the structure of the liver or lung. Immediate examination, however, showed that the needle was properly entered, and that the peculiar fluid was only a highly tinged specimen, and by no means pure blood. The presence of blood under such conditions is ever suggestive of hæmorrhagic effusion due to malignant or tuberculous disease, but the history and symptoms in this instance were not of a character to sustain either theory. On the contrary, it was the opinion of both Dr. Weeks and myself that the presence of blood was due to the state of the patient's system, and to the high degree of congestion of the pleural surfaces. It is not at all impossible that the distention and weight of so much dense liquid favored exosmosis of the blood corpuscles, and ruptured some of the smaller vessels. The remarkable recovery of the patient is confirmatory of the view that the blood effusion did not originate in either tuberculosis or malignant disease.

(6.) Lastly I will say a few words regarding the treatment instituted and carried out after thoracentesis had been performed. As I estimated the case I saw three chief indications for medicinal remedies: —

(1.) To improve digestion and nutrition.

(2.) To promote the action of the heart and kidneys.

(3.) To further absorption by counter-irritation.

In order to meet the first I kept her upon a tonic composed of the fluid extract of cascara sagrada and the tincture of nux vomica given in the elixir of calisaya. I believed that more would be accomplished by stimulating the power and function of her blood-making organs and combating a condition of habitual constipation than by acting more directly upon the entire volume of blood with iron, as is generally advised. Conjoined with these remedies I advised a substantial albuminous diet of milk, eggs, beef, stale bread, and coffee of moderate strength. It is to be ever borne in mind in the treatment of this class of cases that the effusion is highly albuminous, and the demand for a restoration of this vital material to the economy is very great. Excessive waste needs to be counteracted by a corresponding supply.

With a view of stimulating the action of her heart and kidneys, and thereby promoting absorption, I have from first to last maintained the action of carbonate of ammonia given in Trousseau's diuretic wine. Regarding carbonate of ammonia in cases of pleural effusion, Bartholow says that "when an effusion is poured out the only agents which possess the property of resolving it are alkalies, and the most efficient of these is ammonia." The diuretic wine, containing as it does digitalis, acetate of potash, squills, and a mild stimulant, afforded a combination which met well the indication for a heart tonic, diuretic, and alterative.

For counter-irritation, employed with a view of modifying diseased action and furthering absorption, I used a succession of cantharidal blisters over the lower portion of the thorax on the affected side, and also the tincture of iodine. All and all the case is a most satisfactory illustration of the great value of surgical and medical therapeutics.

— A correspondent of the *Medical Record* writes *à propos* of Darwinism and circumcision: "The only explanation I have ever heard given by a scientific man to the fact of Jews continuing to be born with foreskins is the witty repartee, attributed to Professor Huxley, who immediately answered the question, when propounded by a country clergyman, with the quotation, 'There 's a divinity that shapes our ends, rough-hew them how we will.'"

PROGRESS IN DENTISTRY.

BY WILLIAM HERBERT ROLLINS.

A.

1. — DEVELOPMENT OF LOWER JAW.

DR. J. BLAND SUTTON[1] states that the lower jaw is developed from six centres, each one of these corresponding to a separate bone in fishes. The following liable gives the names of the centres of ossification and the corresponding bones in the lower orders: —

Centre of Ossification in Man.	Corresponding Bones in Fishes, etc.
Mento-Meckelian	= Mento-Mechelian.
Angle	= Angular.
Condyle	= Articular.
Coronoid	= Surangular.
Splenial	= Splenial.
Dentary	= Dentary.

In his investigations he took as a guide this rule: "Whenever a nerve passes through a bone it marks the confluence of two or more ossific centres." Applying this to the lower jaw, we have to deal with three nerves: inferior dental, mental, mylo-hyoid. The inferior dental enters the bone by a foramen formed by the union of five ossific plates, the coronoid, condyloid, dentary, angular, and splenial; the nerve then travels in a tunnel formed on the outside by the dentary, and by the splenial on the inner side. The branches which go to the teeth pass up the foramina left between the splenial and dentary plates.

The mylo-hyoid runs in the groove which once lodged Meckel's cartilage.

The mental passes out of the bone through a fenestra formed by the dentary and mento-meckelian ossifications. The paper is too long to give more than a very brief abstract, though it is one of the most interesting investigations of the year.

2. — POLYGNATISM.

Dr. N. Meyer[2] reports a case in a first-born child of healthy parents. At birth there was a swelling about the size of a walnut on the left and outside the normal jaw. As the lower lip was large, a piece was removed eighteen months after birth. The first dentition did not begin till the fifteenth month, but was otherwise normal. At seven years a tooth erupted from the tumor; this was followed by nine others. At the age of fourteen the jaws presented the following appearance: In the upper jaw the teeth were normal. In the normal lower jaw there were four incisors, one canine, two bicuspids, and three molars. The supplementary jaw contained two molars, one bicuspid, two incisors, the other teeth having been extracted.

3. — DOUBLE CLEFT IN PALATE.[3]

The child was four months old. Instead of the ordinary medial fissure there was one on each side. The part between these clefts was one quarter of an inch wide, and extended into the posterior wall of the pharynx, with which it was continuous. The bony septum completely separated the pharynx into two parts. The most probable explanation of this peculiar condition is that the notochord, instead of ceasing at the pituitary fossa, extended further forward, the blastema surrounding it uniting with the plate descending from the coalesced trabeculæ cranii, forming the nasal septum.

4. — UNILATERAL HYPERTROPHY OF LOWER JAW.[4]

The patient was thirty-six years old. The vertical length of right ramus was three inches, that of the left one and a half inches. No cause could be found for the hypertrophy.

5. — EARLY ERUPTION OF MILK TEETH.

Magitot[5] says no interference should be allowed in the case of the early eruption of milk teeth, as in most cases the teeth do regain a certain amount of firmness in spite of their short roots. The only serious inconvenience caused by them is the difficulty of nursing, which may be overcome by artificial teats. A sufficient reason for not extracting is the chance of accidents, particularly of fatal hæmorrhage.

6. — SPONTANEOUS FRACTURE OF THE TEETH.

Several cases have been reported during the year. In each the symptoms have been alike. The patient heard a loud report, as though a gun were fired near the ear. The fractures did not come when the teeth were in use, so that they could not be traced to any hard substance. Various explanations have been given. One writer in describing his case suggests that the explosion was caused by the pressure of gas in the pulp chamber. Colman[6] denies this, as he has seen a fracture of this kind in a tooth with a living pulp. He thinks the cause is calcification in an inflamed pulp. He believes such a pulp is in a condition of tension; when this reaches a point greater than the resistance of the dentine fracture must result.

7. — THIRD DENTITION.

The existence of a third dentition in man has been denied by most writers. A case is reported in the *Dental Jairus* of a man ninety-five years of age who has recently cut nine new teeth, and there is evidence of others not yet erupted.

B.

1. — ORGANISMS PRESENT IN THE MOUTH.

Dr. W. D. Miller gives the following as almost always present: (1.) Leptothrix buccalis. (2.) Vibrio regula. (3.) Clostrydium butyricum. (4.) Mycoderma aceti. (5.) Saccharomyces mycoderma. (6.) Spirochete dentium. (7.) Leptothrix pusilla. (8.) Penicillium microsporum. (9.) Bacterium subtile. (10.) Bacterium termo.

2. — LEPTOTHRIX GIGANTEA.

Dr. W. D. Miller has discovered a new form of leptothrix, to which he has given this name. He has found it in the mouths of cattle, horses, dogs, and hogs. It appears as masses of threads radiating from the point of attachment. The threads are developed from cocci. The older threads are segmented into bacilli and cocci, so that in this fungus there can be no doubt of the connection of these three forms.

3. — RELATION OF FOOD TO TEETH.

Kirk[7] has under his care the teeth of four hundred

[7] Independent Practitioner, January, 1884.

children in the Pennsylvania Institute for Deaf and Dumb. He has observed an entire change in the children's teeth when they have been in the institution for a year. The teeth become so hard that it is necessary to retemper the instruments to make them hard enough to cut the dentine in preparing the cavities for filling. The teeth become more firmly placed in their sockets, making extraction difficult. Many cases of spontaneous arrest of caries and of new formation of dentine are seen. These favorable changes are due to the food, which consists largely in preparations of maize, oats, and wheat, from which the layer just under the silicious coating has not been removed in milling. Such grains, therefore, contain a large proportion of bone-forming material. With these coarse foods a liberal supply of milk and a small amount of meat and sugar are given.

4. — CAUSES OF DEGENERATION OF THE TEETH IN THE BLACKS OF THE SOUTHERN STATES.

Dr. A. A. Hilzim[1] attributes this to the change in food and habits since the abolition of slavery. Formerly the negroes lived mostly on corn-meal and meat. To these were added, for breakfast, coffee; for dinner, vegetables. Sometimes wheat flour took the place of corn, but it was ground on the plantation, and not bolted. This food, served at regular hours and combined with plenty of fresh air, exercise, and sleep, made the teeth strong and hard. Now the negroes eat fine white-flour bread, spend a large part of their wages in sweetmeats, eat at irregular times, and sleep too little.

5. — TEETH IN INHERITED GOUT.

Mr. Duckworth,[2] as the result of an examination of three hundred cases, states that the teeth are remarkably large, regular, and strong. They are well enameled and free from decay. The edges of the incisors are not crenated. The color is yellow. The implantation firm. In these cases there is an abundance of tartar. The teeth are usually lost from absorption of the sockets.

6. — TEETH IN DIABETES.

Dr. Magitot[3] says an examination of the mouth always shows a lesion of the alveolar border. This begins by a slight alteration in the position of the teeth. Then follows an alveolar catarrh, which results in a marked absorption of the alveoli, causing the teeth to loosen and drop out, if the patient lives long enough.

7. — TEETH IN LOCOMOTOR ATAXY.

Dr. P. J. Thompson[4] gives the appearance of the teeth and jaws in two fatal cases. In the first case sections of the trifacial nerve near the pons Varolii showed sclerosis; the white substance had disappeared; the axis cylinders were choked in a bed of connective tissue; a few nervous bundles were healthy. In the second case both trifacial nerves were much atrophied, the left one being reduced to a thin gelatinous filament; the Gasserian ganglion on the same side was a flattened band of connective tissue. In both these cases the teeth had been lost, and the jaws presented a senile appearance from the absorption of the alveoli. These changes were thought to be caused by the sclerosis of the trifacial.

3 British Journal of Dental Science, page 473, 1883.
4 British Journal of Dental Science, page 18, 1883.

8. — TEETH IN INHERITED SYPHILIS.

A. Fournier[5] defines a syphilitic tooth as one whose development has been arrested in the intra-follicular state by syphilis. The results are arranged under four heads: Dental Erosions, Microdontism, Dental Amorphism, Vulnerability. Dental erosions are of many kinds. They consist of a more or less grooved or pitted condition of the enamel. The most important from a diagnostic point of view is the curved border of the incisors, to which the name of Hutchinson is attached. Fournier does not feel quite sure that other diseases may not cause this. (Magitot, in a paper read before the last International Medical Congress, stated that these grooves were caused by eclampsia.) The other erosures are not of much diagnostic value, as many other diseases may produce them.

Microdontism. This is a diminution in the size of the teeth. It is never a characteristic of the entire denture, and is usually confined to a single tooth standing among well-developed neighbors.

Dental Amorphism. This shows itself in several ways: (1.) Some tooth, a canine for example, takes the form of an incisor. (2.) Additional cusps may appear; the first molar often has a well-developed cusp on the side. (3.) The incisors take the form of axe blades, the crown being much too large for the necks. (4.) One or more teeth lose their characteristic form, and appear as irregular masses of enamel and dentine.

Vulnerability. The statements which the writer makes here are too vague to be of any diagnostic value.

C.

1. — EXTRACTION FOR REGULATING.

It has always been a matter of dispute which teeth should be taken out where room is required in regulating. At almost every dental meeting this subject comes up, and very rarely is anything more reliable than personal opinion advanced. Dr. Perry has attacked the problem in a sensible way, and gives his results in *British Journal of Dental Science*, January 1, 1884. He has tabulated 7277 extractions for disease, and finds that 2823 of these were first permanent molars, 737 were first bicuspids, and 944 were second bicuspids. As the statistics show that more first molars are lost than bicuspids we should, as a general rule, take out the first molar where the choice must be, as is usually the case, between this and a bicuspid.

2. — TRANSPLANTATION OF TEETH.

Dr. Redard read a paper at the last meeting of the French Association for the Advancement of Science, held at Rouen, in which he stated that out of seventy-seven cases seventy-five were successful. The operation is as follows: After extraction hold the tooth in a cold, wet cloth, and cut off the end of the root. Syringe out the socket with a weak germicide; then replace the tooth as soon as possible.

3. — FRACTURE OF JAW.

A curious case is reported in *British Medical Journal* for September 15, 1883. The patient, in falling, struck with his lower jaw a beam, which made a small cut. This was the only evidence of the accident. Two

5 Dental Cosmos, January, February, March, 1884.

weeks later, while eating, he felt as if struck by a blow. An examination revealed a fracture.

4. — NEURECTOMY OF INFERIOR DENTAL.

Dr. Sonnenberg[1] describes a new operation. The patient's head is held firmly back. An incision is begun one centimetre in front of the angle of the jaw. This is carried forward along the edge of the body for four centimetres. The inner surface of the bone is cleaned up to the internal lateral ligament. The insertion of the internal pterygoid is cut; a blunt hook is passed around the nerve, which can then easily be brought to the external opening, and a piece removed. The advantages are: a small wound; the operation is an easy one; there is little bleeding; the capsule of the submaxillary gland is not cut; the wound is a favorable one for healing; and, lastly, the scar is small and not conspicuous.

5. — TRANSFUSION FOR HÆMORRHAGE FOLLOWING EXTRACTION OF A TOOTH.

The patient, a soldier, aged twenty-two. The bleeding was at first slight, but continued all night. Plugging the alveolus, cautery, ergotin. perchloride of iron, ice, and various other things were tried. Ten days after the operation, the patient being almost dead, four ounces of blood were injected into the cephalic vein. The patient rallied, but the bleeding increased. A second transfusion was tried next day. During the operation the heart stopped. The length of time the heart remained quiet is not given. It began again, and from that time the patient made a rapid recovery.

6. — UNITED FRACTURE OF TEETH.

Dr. Van Horne reports[2] a case of fracture of an upper lateral, near the alveolus. A year after the accident the tooth was alive and firmly united.

(To be concluded.)

Reports of Societies.

ONE HUNDRED AND THIRD ANNUAL MEETING OF THE MASSACHUSETTS MEDICAL SOCIETY.

PRELIMINARY DAY.

ON Tuesday, June 10th, as is the custom, the Fellows of the Massachusetts Medical Society were entertained after the manner common to the day preceding that of the annual meeting of the Society.

AT THE HOSPITALS.

At ten o'clock A. M. the Fellows responded to invitations from the Massachusetts General, the City, the new Children's, and the Lying-in Hospitals, at each of which they visited the wards and witnessed certain operative procedures.

At the City Hospital the visitors were shown through the surgical wards, which presented a very attractive appearance. and where were found many cases of unusual interest. The plaster posterior splint so generally used here in treatment of fractures of the leg, and which was the subject of a paper during the afternoon, was found in the various wards in its different applications. One of the cases of interest was a congenital dislocation of the hip in which an attempt is being made to restore the head of the femur to its proper position. At the rear of the main buildings could be seen the tents in process of erection for summer use. In the operating room the femoral was tied for aneurism of the calf by Dr. Homans. Several cataracts were removed by Dr. Wadsworth. Other operations of everyday occurrence were also done. The traumatic surgery of the hospital was exemplified by the case of a boy who had shattered his hand by a cartridge which he had exploded by a hammer. The boy was brought into the hospital during the visit. The application of plaster of Paris to the treatment of club-foot was also shown.

AT THE NEW MEDICAL BUILDING.

At twelve o'clock M., and at the new Harvard Medical building, the Fellows listened to an address by PROF. H. P. BOWDITCH on Methods of Instruction and Research in Physiology, with Demonstrations. Professor Bowditch received the Fellows in the lower lecture room, and there explained the arrangements which adapted the room for experimental lecture courses. Also described the lecture table with its movable central portion which can be wheeled into the physiological laboratory for the preparation of an experiment and be brought into place again for demonstration in the lecture room. A duplicate central portion is similarly used in the chemical laboratory, the lecture room being common to both departments. The fixed portion of the table contains at one end a pneumatic trough, at the other a sink, and is also supplied with gas, water, electricity, and compressed air. The convenience of the blackboards serving also for suspension of diagrams by means of a brass rod at the top and being movable by weight and pulley was explained. A hood revealed by pushing up the blackboards, and useful in experiments which develop unpleasant odors, was shown.

The Fellows being then invited into the physiological laboratory, witnessed experiments connected with original work now in progress and examined the apparatus, which had been arranged for their inspection. The demonstrations were the following: —

(1.) Blood pressure experiment on dog under ether and morphia. Effect of irritation of vagus nerve on rate of heart beat.

(2.) Study of the vaso-motor nerves of cat under ether and curare. Effect of irritation of sciatic nerve on size of leg recorded by means of the plethysmograph.

(3.) The same experiment with frog's legs.

(4.) Demonstration of the action of the semilunar valves of the ox.

(5.) Demonstration of the force of ciliary motion on the mucous membrane of the frog's mouth.

(6.) The effect of changes of temperature on the rate of beat of the frog's heart.

PROFESSOR DWIGHT'S ADDRESS.

Prof. Thomas Dwight then met the Fellows in the anatomical lecture room, and addressed them on Modern Methods in Anatomy, with demonstrations. After an eloquent acknowledgment of the debt which modern anatomists owe to the pioneers of anatomy, Professor Dwight showed how errors still extant in modern works on anatomy are being corrected by the study of the anatomy of frozen subjects. Among others he instanced the position of the stomach, long and generally supposed to be horizontal, but really markedly oblique; also the form and relations of the liver, the shape and relations of the pharynx, etc. He then exhibited very fine frozen sections prepared by himself, and demonstrated the relations of various parts, thus showing the immense value of these sections. Proceeding to say that of all anatomical preparations he considered corrosion and metal methods superior to all others, he exhibited very beautiful examples of these methods, the corrosion specimens having been prepared by himself, and the metal specimens (in which Wood's fusible metal was used) by Dr. Mixter. He also showed a "soft preparation," an arm of the well-known case in which the humerus disappeared. The muscles were still flexible, and color good, although the preparation was made twelve years ago. Glycerine was the principal element in the preserving material. Dr. Dwight advocated this method of preservation for use of teachers.

Following his address Dr. Dwight invited the Fellows to a closer examination of his extremely fine models and preparations. The Anatomical Museum is a handsome room, but, very unfortunately, darkened by the masses of wood-work, in the place of which light iron should have been used.

At three o'clock P. M. the Fellows were called to order in Huntington Hall by President Hosmer to listen to the paper of Dr. George W. Gay, of Boston, on

THE PLASTER POSTERIOR SPLINT IN THE TREATMENT OF FRACTURES OF THE LEG,

and witness its practical application.

After explaining the nature and uses of the splint Dr. Gay, with a corps of assistants, made and applied the same to subjects. The material which forms a basis for the plaster is ordinary gauze. Measurements of the patient's leg having been taken, several thicknesses of gauze are so cut as to fit the leg when applied. The outside layer of gauze is tongued along its edges, and after the plaster paste has been applied and worked into the layers of gauze these tongues are brought forward and lapped over the inside layer, and thus bind the whole firmly together. A roller bandage of soft cotton-flannel having been already applied to the leg of the patient the splint of gauze and plaster is applied over this, its edges being brought from behind forward and lapped over the leg in front until they meet in the median line. An ordinary roller bandage is applied over this, and the splint is complete. Its advantages are (1) that it adapts itself to a rapidly swelling leg, its anterior edges invariably separating in direct ratio with the pressure, and thus need not be removed; (2) that the surgeon can apply it to any form of fracture, and leave it for the night without fear of sloughing or gangrene from unrelieved swelling, etc.; (3) the outer bandage and the splint can be removed without injury to the splint, which can be reapplied as firmly as before by means of straps which buckle; (4) it is a splint always open in front, and never requires to be cut open as in the old form of plaster splint, which often was spoiled during removal.

The Adjourned Meeting.

At four P. M. in the same place the Society held an adjourned meeting in accordance with the vote passed at the last annual meeting. President Hosmer in the chair.

ADOPTION OF THE CODE.

Upon opening the session the President called attention to the fact that the Code of Ethics, although accepted by the Councilors, had never been adopted by the Society, and asked for a motion. It was moved and carried that the Code be adopted.

COMMITTEE ON LEGISLATION.

Dr. H. O. Marcy then offered the ensuing motion: "*Resolved*, That a committee of one from each District Society be appointed with authority to secure from the Legislature an enactment to protect the public from incompetent and irregular practitioners of medicine."

This motion won an affirmative vote.

The Committee appointed is as follows: G. W. Doane, Barnstable; H. M. Holmes, Berkshire; N. Paige, Bristol North; J. Dwelly, Bristol South; W. Cogswell, Essex North; G. Osborne, Essex South; F. J. Canedy, Franklin; W. Holbrook, Hampden; F. Nickerson, Middlesex North; G. J. Townsend, Middlesex South; J. M. Harlow, Middlesex East; J. Stedman, Norfolk; B. A. Sawyer, Plymouth; H. O. Marcy, Suffolk; J. O. Marble, Worcester; J. P. Lynde, Worcester North.

AMENDMENT OF THE BY-LAWS — ADMISSION OF WOMEN.

Dr. H. I. Bowditch then offered this motion: — *Resolved*, That the first four lines of By-law I. be stricken out and the following be substituted: "Candidates for admission into the Massachusetts Medical Society may be either *male* or *female*, and every candidate must by proper credentials and examination satisfy the Censors of said Society that he possesses the following qualifications," etc.

The President at once ruled that this motion was out of order, because at a meeting two years ago the Chair decided that a similar motion might be discussed by the Society, but that no amendment of a By-law could be made until it had been first referred to the Council, and the President was at that time sustained in his decision. Dr. Bowditch's motion, therefore, was not in order.

Dr. Bowditch appealed from this decision, and asked why a Fellow of the Massachusetts Medical Society could not propose an amendment to the By-laws.

The President simply repeated his former statement.

Dr. Hodgdon, with the remark that if a president from purest motives make a wrong decision, and this be shown by the common feeling of the Society to be inconsistent, such president should at once recede from his position, seconded Dr. Bowditch's appeal.

The President then said that the decision was not his, but was made by a former president and sustained

by vote, and therefore was now parliamentary law. Dr. Bowditch's motion was consequently out of order.

DR. MILLET asked, "Suppose we decided *any* question two years ago, is that a reason why we cannot to-day vote to annul what we then did?" It must be so. Any society can rescind a vote. We cannot take away the chartered rights of the Council, but we can rescind any move. We can also unmake the Council we have made. Councilors have certain rights under the Charter, but they cannot act independently of the Society.

DR. DAVID HUNT was surprised that there could be any question of the right of the Society to change By-laws. The Charter, in Section III., in so many words gives that right.

DR. GEORGE C. SHATTUCK said: I understand that this practice of referring matters to the Council is a manner of facilitating work, as in boards of directors in corporations. Business is better done when the Board first consider a motion or amendment and then submit their decision to the larger body. We have over fifteen hundred members. Not one fourth of them are here. The Councilors are always well represented. Their decision is a fair one. Here a decision would not be fair. We have a right to change a By-law, but is it wise to do so before referring the matter to the Council? A quorum of ten Fellows is a legal quorum, so that even that number could make a change in the By-laws. This arrangement of reference is a convenience. It is a pity that any man should try to break it down in order to bring a particular question before the Society.

DR. HODGDON thought discussion irrelevant. His point was that on any subject it was impossible for the Society to recede if the ruling of the Chair be sustained.

DR. HOLMES, of Lexington, thought that *if* only one fourth of the Fellows were present it was due to lukewarmness. Why, then, cannot those who do come act?

After further discussion the CHAIR again said the ruling could not be changed, because it was law.

DR. E. T. WILLIAMS, of Roxbury, thought the ruling of two years ago illegal. If the Council pass a By-law they can reconsider but not amend it. Now the Society cannot amend a By-law, and thus nothing can be done. This must be illegal.

The CHAIR then said he was bound by all usage to hold to his ruling. If he be bound illegally then such limitation should be changed. According to Cushing a sustained ruling must act as a precedent for future action. If a law is clear it is understood. If equivocal it should be referred to competent authority. The Society is competent, and I think cannot admit that it can go behind this law.

DR. CUTLER moved that the decision of two years ago be reconsidered. Motion was seconded.

DR. C. P. PUTNAM said discussion was not in order. Whoever heard of a Chair who had the power to say a motion was out of order. The Society is the only power to say whether a motion be in order. If the Society interpret in a way differing from the Chair they have power to do so.

DR. WILLIAMS said the decision of the Chair had been appealed from. Any ruling can be appealed from. The appeal is the only question which can be considered.

DR. C. P. PUTNAM rose to a question of order, and asked whether the Chair decided that the motion of Dr. Cutler was before the house.

The CHAIR replied that the motion was not in order because the Society was not competent to change a By-law.

DR. MILLET appealed from this decision.

DR. WILLIAMS asked as to which appeal was before the meeting.

The CHAIR said it was Dr. Millet's appeal.

DR. WILLIAMS said that was a point of order, because the first appeal had been seconded, but not settled.

The CHAIR replied that the first appeal was not an appeal from the ruling of the present Chair, and therefore was no appeal.

DR. WEBBER inquired whether the appeal did not relate to a ruling of the Chair.

The CHAIR replied that the Chair did not rule, but that the Chair's decision was parliamentary law.

DR. WEBBER asked, "Is not that a ruling of the Chair?" Chair: "Yes." Several voices: "We appeal from that decision."

In this way the snarl began to unwind itself. The Chair naturally was forced to call upon the Society for votes sustaining the Chair in reference to Dr. Bowditch's appeal. The vote was *viva voce*, and decided in the negative. The Chair was not sustained.

Dr. Bowditch's motion was then recalled.

DR. MORSE, of Watertown, said the Society to-day was taking a stand which endangers its By-laws. Any number of Fellows can thus change the By-laws. The dignity of the Society is being threatened.

DR. BOWDITCH remarked that he expected his motion would be referred to the Councilors.

DR. BRONSON said that for many years this question has been presented to the Society, and sometimes before the Council. It must originate somewhere. According to the By-laws, if the question were decided in the affirmative by the Society it will be referred to the Council. It has been said that the Council does not fairly represent its constituents. Then that is the fault of the constituents who elect the Councilors. It was his opinion that if as a Society we design to carry out the convictions of our fathers, we meet to help the progress of medical science; and therefore he believed that any person of whatever sex or color who can answer the requirements should be admitted to the Society. Whatever the Fellows do here is a work of district societies done in mass. He asked for moderation. If the Fellows cannot get what they want to-day they can secure it legitimately one day by acting through the District Societies.

DR. HARVEY said the whole trouble of to-day is: Our By-laws do not provide the means by which these By-laws may be altered or amended. They are not explicit. The By-laws do say that a By-law cannot be changed without concurrent vote of Society and Council, but *not* how they can be changed or amended. In our District Societies By-laws may be changed if notice be given at a previous meeting. Notice of this motion to change a By-law was not given at a previous meeting, and therefore I think the Society should not be prepared to act. The question of the admission of women is not my point. I refer to the changing of By-laws in this way. It is not right thus to annul By-laws. I do not say the Society has no right to change By-laws. I merely say that no way to do so is provided. This is an innovation.

A Fellow asked, "Does not the action of the Society, in the absence of a By-law, establish a precedent?"

Dr. Harvey replied that this was precisely the point on which the President made his decision. It was a reference to a precedent.

The question was then called and a rising vote counted by tellers appointed by the Chair.

The decision was 209 ayes, 123 noes, and thus the motion passed.

It was then moved that Drs. H. I. Bowditch and Morrill Wyman be authorized to present the result of the vote to the Council that evening. Decided in the affirmative. And, to complete the details of this subject, the matter was presented to the Council, discussed, and the vote confirmed by another strong affirmative.

OFFICERS FOR 1884–1885.

During their meeting the Councilors appointed the officers of the Society for 1884–1885, as follows: —

President, Charles D. Homans, Boston; Vice-President, A. C. Deane, Greenfield; Treasurer, Frank W. Draper, Boston; Corresponding Secretary, Charles W. Swan, Boston; Recording Secretary, Francis W. Goss, Roxbury; Librarian, E. H. Brigham, Boston; Orator, F. K. Paddock, Pittsfield; Anniversary Chairman, Robert Amory, Boston.

On the Committee on Finances E. G. Cutler, of Boston, was appointed vice C. D. Homans. On the Committee to Procure Scientific Papers H. P. Walcott replaces Dr. Paddock, otherwise the committees remain unchanged.

The One Hundred and Third Annual Meeting

of the Society was called to order by President Hosmer in Huntington Hall on Wednesday, June 11th, at nine A. M.

RECORDS, ADDITIONS, AND DEATHS.

Records of the preliminary and annual meetings of 1883 were read by Secretary Goss, also the records of the meeting of the previous day. The Secretary then read a list of Fellows admitted since the last annual meeting, in all ninety-seven. Then followed the names and ages of Fellows deceased during the past year, thirty in all — their average age being fifty-nine and two third years. Readers of the Journal may not have observed that the average age of deceased Fellows has been given in this report during the past seven years. During this period this is the first time that the average age has sunk below sixty-two. This is a remarkable average, in view of the fact that in all vital statistics the average age of the physician is set at thirty-eight years.

THE EXAMINATION OF CANDIDATES.

Dr. Millet presented the following preamble and resolution: —

Whereas the Charter of the Massachusetts Medical Society imposes upon the Censors of said Society, under a penalty, the duty of examining all persons who are desirous of obtaining a license, or letters testimonial, of their qualification to practice medicine and surgery in this Commonwealth; therefore,

Resolved, That the Censors of the Massachusetts Medical Society are hereby instructed and required to examine all persons, whether male or female, without reference to the time when, or place where, they acquired their medical education, who apply for such examination, without reference to admission to said Society; and such letters testimonial when issued shall entitle the holder to all rights and privileges of regular practice excepting membership of the Society.

In presenting his resolution Dr. Millet said that in 1859 the Legislature by a law undertook to dictate who should be members of the Society, though the Legislature had no reserved right to change the Society Charter. And he made the remarkable statement that since 1859 the Council has had no right to elect honorary members, and that such honorary members as within that time have been elected have been elected illegally. After reading his resolution Dr. Millet expressed the opinion that if the course therein set forth had been adopted this Society would not now be in its present dilemma.

Some discussion followed, and the motion was made that the whole matter be referred to the Standing Committee on By-laws of District Societies. Carried by vote in the affirmative.

TREASURER'S REPORT.

Dr. F. W. Draper, Treasurer, then read his annual report, which showed that the Society has in invested funds $32,420.17.

Income for the year	$7963.75.
Balance from old account	1539.42.
	$9503.17.

Outgo: —

Expenses of last annual meeting	$1818.78.
Other expenses	6121.53.
Balance to new account	1562.86.
	$9503.17.

Number of Fellows now on the Catalogue, 1529.

READING OF PAPERS.

An interesting paper on A Case of Chylous Deposit in the Abdomen was then read by F. Nickerson, M. D., of Lowell.

L. Huntress, M. D., of Lowell, next read a highly scientific and valuable essay on The Pitch of the Percussion Sound. This paper elicited remarks from Drs. Bowditch and Garland, who expressed their sense of its value.

An essay on Sanitary Forest Culture, by J. F. A. Adams, of Pittsfield, next followed. It aroused much interest, and the subject was discussed by Drs. Marcy and Blodgett.

Dr. Millet then moved that the subject of tree forestry be referred to the Legislative Committee already appointed, with the request that they bring the same in proper form before the Legislature.

The motion received an affirmative vote, as did Dr. Bowditch's suggestion that Dr. Adams be added to this committee.

An instructive paper on Weight as an Indication of the Character of Risks for Life Insurance was then read by J. Seaverns, M. D., of Roxbury. Dr. Seaverns made a very generous distribution of printed statistics in relation to over and under weight.

Dr. C. W. Swan then read a Health Communication from the Secretary of the Middlesex North Society.

PRESENTATION OF DELEGATES.

The following delegates were then presented by the President: Dr. G. G. Hopkins, of the New York State Medical Society. Dr. E. North, of the New Jersey State Medical Society. Dr. C. M. Carleton Connecticut State Medical Society. Dr. Chas. O'Leary, Rhode Island State Medical Society. Dr. E. A. Pond, from the State Medical Society of Vermont.

Each delegate made felicitous remarks.

After an intermission of fifteen minutes the Annual Discourse was delivered at twelve M. by the orator, JOHN CROWELL, M. D., of Haverhill. At its termination the orator received a vote of thanks for his valuable and interesting address.

THE DINNER.

At one o'clock, P. M., the Fellows marched in the usual order to the Skating Rink, on Clarendon Street, where the annual dinner awaited them.

The Committee of Arrangements deserve great credit for their manner of seating the Society and its guests. Instead of placing the orator and invited guests on the side of the hall they were placed at tables upon a raised platform at the end of the hall. This not only was more convenient and suitable, but by this arrangement the speeches were much more distinctly heard.

Grace having been pronounced by the Rev. Dr. Courtney, the annual attack began. The dinner was unusually bountiful and enjoyable.

Upon the platform, on either side of the Anniversary Chairman, Dr. George B. Shattuck, sat his excellency Governor Robinson, Dr. Mackie of New Bedford, Surgeon-General Holt, the Rev. Frederick Courtney, Samuel Eliot, LL. D., Dr. George C. Shattuck, Dr. J. O. Green, of Lowell, Dr. Jarvis, Dr. Henry I. Bowditch, Mr. H. O. Houghton, the president-elect of the Society, Dr. Charles D. Homans, the retiring President, Dr. Alfred Hosmer, of Watertown, the orator, Dr. John Crowell, of Haverhill, ex-Mayor Dr. S. A. Green, Dr. Ira Russell, of Winchendon, Dr. H. P. Walcott of the State Board of Health, and Dr. Geo. D. Hersey, Secretary of Rhode Island State Medical Society.

DR. SHATTUCK'S ADDRESS.

Shortly after two o'clock Dr. Shattuck called the assembly to order and addressed them as follows: —

Fellows of the Massachusetts Medical Society, — It is my duty as your Anniversary Chairman, in behalf of my colleagues who compose your committee of arrangements, to welcome you to these festivities which it is the custom of our Society to provide at this season of the year as a fitting termination of our annual meeting, — festivities at which its own officials, the dignitaries of the State, distinguished representatives of other State medical societies, of other professions and pursuits in life, become our honored guests. It is my privilege also to congratulate you upon coming together to this eighty-third annual dinner, once again as so often before in such goodly numbers from all parts of this State to show your respect for this organization, your interest in each other and in each others' work, and your appreciation of the benefits which accrue to you from your membership.

The Society has already fairly emerged from the period of reminiscence and celebration, incident to the completion of the first century of its existence, and is quietly at work making the records for the history of its second century, of which let us hope it may have no reason to be less proud than of the first. The past year has simply been one, like many others, of quiet steadfast work and duty conscientiously performed, years which are really as much more important than the epochs they go to make up as the creator is more important than the created. It is not, however, for me to detain you to tell you these things of which you are well aware, in regard to the past of the Massachusetts Medical Society, of which you feel secure. Our newly-elected president will perhaps prognosticate the future for you, and some of our distinguished guests are ready by this time, I am sure, with spontaneous words of encouragement and sympathy. I hasten to anticipate your impatience to hear them. In calling upon your new president, Dr. Charles D. Homans, to respond to the first toast of "The Future of the Massachusetts Medical Society," I shall venture to remind you that it is not the first time the name of Homans appears among those of your presidents, his father, Dr. John Homans, having presided over the meetings of this Society between the years 1859–1862. That knowledge of the past history of the Society which he must possess should help him to forecast the future, however full of changes.

DR. HOMANS' RESPONSE.

DR. HOMANS responded very briefly. He stated that in 1789 there were sixty-eight members of the Society, against 1529 in 1884. This was certainly a wonderful and most gratifying increase. There had been ninety-four new members added during the present year. Dr. Homans alluded to the action of the Society in admitting women, and remarked that perhaps twenty or thirty years hence the present scene would be a ball-room.

SPEECH OF EX-PRESIDENT HOSMER.

The next toast called upon the retiring President in the following words: —

"The official life of him who has been your President the past two years expires to-day. It is, however, hard to associate even official mortality with one of so much vigor; and we associate, rather, many useful years in which what his hands find to do we may be sure will be done with all his might, with the name of Ex-President Hosmer."

DR. ALFRED HOSMER, of Watertown, the retiring President of the Society, responded to the toast as follows: The subject of the Massachusetts Medical Society is a theme which can easily be expanded into a discourse so long and so large that this audience would hardly care to receive and digest it at a single session. Without penetrating its substance, I shall simply touch a small part of its surface, and leave it for the first guest of the day to serve such portion as he pleases as one of the courses at the next annual dinner. As undue importance may be attached to the words of the moribund, perhaps I ought to be cautious in respect to those utterances which are connected with the dissolution of the last tie that binds to official life. Inasmuch as moral qualities enter so largely into the constitution of good citizenship, and as this organization of ours is not wanting in analogy with that compact known as society, whose criminal laws are not always adequate, and whose civil laws sometimes almost forfeit their right to the name, I may, without breach of propriety, allude to matters ethical. I do not do this in the larger sense which includes what our Society has long needed, as much for the convenience as for the control of its Fellows, namely, a well-constructed and comprehensive Code of Ethics, but in a smaller way, that relates to something which is near to us on every side. I would speak of that which either is an obligation made up of three inseparable parts or consists of three duties so closely allied and so intimately connected that neither one can be neglected without detriment to the other two, while the performance of any

one is the discharge of all. I mean the duty which every Fellow owes to the profession, to this Society, and to himself. This triple duty: let every Fellow discharge it without reserve and without presumption, and he will raise the profession, and rise with it, to a higher level of character; he will find in this Society a pride that will never cease to increase; and he must possess that self-respect without which there is no true manhood; and no one can become a physician, deserving the name, unless he first be a man.

GOVERNOR ROBINSON.

Our loyalty to the State, said Dr. Shattuck, is gratified and encouraged this year, as we always would like to have it, by the presence of his excellency the Governor. There are many departments of the State which attract more attention than those concerned with public health and what is now known as State Medicine, there are few of more vital importance to the welfare of the people, and none in which the administrators should be more carefully selected. Governor Robinson needs no introduction to a Massachusetts audience.

A hearty and vociferous greeting met Governor Robinson, who said: Let me bring to you the congratulations of the Commonwealth. Personally I rejoice to see so many of you present to-day. With all the satisfaction that you may take to yourselves I think of the many at home, your patients, who are having their day off also. Seriously, gentlemen, the only duty of the doctor is not in attendance in the sick room. With your education and skill you are something to the community and the State. No man educated to the practice of medicine has done his whole duty when he has taken care of the sick, reaped his profits, and settled down to the results. Ideas gained ought to stimulate to greater good, and the discussion of great questions relative to the people at large. "Governor," I was asked before dinner, "how shall you feel when you stand before a thousand doctors?" My reply was: "There's no danger if I keep my mouth shut." One cannot do justice to this occasion unless ready to recognize the great advance in the science and practice of medicine. Gentlemen, to-day we wonder at the uncertainty, dimness, and error through which these have groped. Honor to them, for they wrought out this advance. I, for one, congratulate you on the step you took yesterday. If a woman can cure me, or my children, or my wife, God bless her to do it. If the man can do it better give him the chance. Why, who objects to woman joining a fellow? In conclusion, the Governor said that as the seven-year term of the medical examiners would expire in a few days he had a good chance now to pick out the proper men for these places. Gentlemen, he continued, I ask you in all plainness and without reserve, will you come to the executive and tell him if you know a man on the present list unfitted for his place?

The Governor then made a strong appeal for maintaining the honor and dignity of the profession, and wished that the next century of the Society's history might be as useful as the last.

REV. DR. COURTNEY RESPONDS FOR THE CLERGY.

Dr. Shattuck then read the ensuing toast: —

The Clergy. "There are three classes of skilled professionals whose duties unite them so closely to the wants and rights of men as to make them necessary advisers and aiders in securing and protecting them in their individual possession of life, liberty, and happiness. They are the curés of souls, the curés of bodies, and the curés of property and personal rights, the Doctors of Divinity, the Doctors of Medicine, and the Doctors of the Law. All three classes of sick are 'halt and lame and blind,' all three are patients and clients, and all three classes of healers are Doctors, Counselors, and Ministers alike."

This excellent statement was lately made by a Doctor of Laws when addressing a meeting of Doctors of Medicine. As a Doctor of Medicine I now reproduce it in addressing a Doctor of Divinity, and call upon the Rev. Dr. Courtney.

The Rev. Frederick Courtney alluded to the temptations he felt to preach a good square sermon; he would, however, remember Bishop Wilberforce's story, that a good preacher was one who could take an audience after a good dinner, on a summer afternoon, and not allow one of them to go to sleep. Dr. Courtney drew several illustrations from the Scriptures not at all complimentary to the profession. But the clerical profession is in the same boat as the medical, he said, as far as calumnies go. Another point of resemblance is the conservatism of both professions. I suppose the opinion of those present is divided as to the advisability of admitting women to the Society. Perhaps, too, the medical profession, like the clerical, is given to a dislike of innovations; and I don't know that the *odium theologicum* is worse than the *odium medicum*, shall I call it? Another thing that troubles us both are the quacks. Dr. Courtney then spoke of the growing severance of the medical profession from Christianity, deprecating this tendency, which he feared was an increasing one.

MR. JUSTICE FIELD, OF THE SUPREME COURT.

The next speaker was introduced as follows: —

"Sir Edward Coke, as you know, is responsible for the statement that 'law is the perfection of reason.' But the judicious Hooker, in his Ecclesiastical Polity, tells us in words, which though often quoted, never lose their rotund sonorousness, that 'of law there can be no less acknowledged than that her seat is the bosom of God, her voice the harmony of the world; all things in heaven and earth do her homage, the very least as feeling her care, and the greatest as not exempt from her authority.' All this is represented to us to-day by Mr. Justice Field, of the supreme judicial bench of the State."

Mr. Justice Field in reply said: It was at one time thought to be the policy of this State to furnish patients for the doctors by overworking its judges. You have been many times before the court as witnesses, and I trust you have always been fairly treated. The law, medicine, and divinity are the three ancient professions. Yours is the oldest. You were doubtless called in when Eve ate her first apple, — if it was a green one. Medicine and law are closely connected. There are medico-legal societies and books on medical jurisprudence. Both professions are exposed to quacks, though yours is worse off in this respect; there are no Indian lawyers, nor vegetable lawyers, nor electric lawyers. In one sense yours is a suicidal profession; it is your duty so to promote the health of the people as to make doctors unnecessary. But I hope the members of this Society will not be so far diminished that you

cannot celebrate this anniversary through the coming generations.

THE ORATOR OF THE DAY.

The chairman introduced the orator of the day, Dr. Crowell, as follows: —

"I think our having heard the orator of the day before dinner upon the Physician as a Popular Educator makes us only the more desirous to hear from him after dinner, and I call upon Dr. Crowell to say something in favor of the scientific investigator."

DR. J. CROWELL, in response, told the story of an eccentric divine who once said to his audience, "My hearers, there is a great deal of ordinary work to be done in the world, and, thank the Lord, there are a great many ordinary people to do it." As one of the ordinary workers, said Dr. Crowell, I wish to speak in behalf of this great majority, and express thanks to those extraordinary workers who do so much for us in the way of patient research and investigation. Dr. Crowell concluded by saying that the specialist has also done great service in curing the ordinary doctors of a certain false modesty in professional fees. The country doctors were plodding on in the old-fashioned way of small charges and long credit until our metropolitan friends came to the rescue, who received the fee of fifty or a hundred dollars with such a graceful nonchalance as to give great moral courage to their suburban brethren. With this worthy stimulus before us, we do now venture to charge two dollars a visit and five dollars for a consultation.

Other speeches were made by DR. SAMUEL ELIOT and PROF. W. T. SEDGWICK of the Institute of Technology, and letters of regret were read from DR. J. S. BILLINGS, of Washington, and PROF. R. T. HOWARD, of the McGill Medical College, Montreal.

The occasion was in every way successful and enjoyable, but might it not be suggested that if speakers at these annual dinners would but give the active principle (the alkaloid as it were) of what they have to say the speech-making would not only consume less time, but more speakers could be heard by that large number of Fellows who invariably are forced to seek their trains in the very middle of this pleasant feature of the entertainment? Nearly seven hundred Fellows were present. At intervals music of excellent quality was provided by the Germania orchestra.

MASSACHUSETTS MEDICAL SOCIETY.

COUNCILORS' MEETING.

THE annual meeting of the Council was held at the Medical Library, Boston, on the evening of Tuesday, June 10, 1884. One hundred and sixteen councillors were present. The meeting was called to order by PRESIDENT HOSMER at seven o'clock.

After the reading of the record of the previous meeting by the Secretary, and its acceptance, the roll of those composing the Council for the year 1884–85 was read. The Secretary announced the names of ninety-seven Fellows who had been admitted during the year, and of thirty who had died.

FINANCES.

The Treasurer's report showed the year's receipts — including a balance of $1539.42 from the previous year's accounts — to be $9503.17. The disbursements amounted to $794.31, leaving a balance of $1562.86. The invested funds of the Society amount, as in the previous year, to $32,420.17. The Society now bears upon its catalogue the names of 1529 members. In accordance with the recommendation of the Committee on Finances, reporting through Dr. Homans, it was voted that $1328.43, being eighty-five per cent. of the balance remaining in the treasury, be distributed among the District Societies. In accordance with the recommendation of the same committee it was voted that the Treasurer sue two Fellows for their dues and remit the dues to two others.

REPORT OF COMMITTEE ON MEMBERSHIP.

DR. AYER, for the Committee on Membership and Resignations, reported a list of names of those desiring to become retired members, and of those wishing to resign. The Council voted in accordance with the recommendations of the committee. Several others were dropped from the roll for delinquency in assessments.

REPORT OF COMMITTEE ON PUBLICATIONS.

DR. SHATTUCK, for the Committee on Publications, reported that no essay had been received in competition for the Society's Prize. Also, that the committee were averse to subscription by the Society to the "Quarterly Epitome." The report was adopted.

REPORT OF COMMITTEE ON BY-LAWS.

DR. PRESBREY, for the Committee on By-laws of the District Societies, presented a report which stated that some of the District Societies have by their By-laws "Committees on Ethics." Inasmuch as a district society has nothing to do with ethics and discipline, and can invest a so-called Committee on Ethics with no powers which do not already belong to its members by virtue of their membership in the Society, such a committee is superfluous, and ought not to exist, and any district by-law whose purpose is to create and empower such a committee is liable to mislead and embarrass, and ought to be abolished.

It was voted to accept the committee's report.

ELECTION OF OFFICERS.

At this stage of the meeting the Committee on Nominations reported the following list of candidates for the offices of the Society for the ensuing year, and the same were elected by ballot: Dr. Charles D. Homans, Boston, President; Dr. Adam C. Deane, Greenfield, Vice-President; Dr. Frank W. Draper, Boston, Treasurer; Dr. Charles W. Swan, Boston, Corresponding Secretary; Dr. Francis W. Goss, Roxbury, Recording Secretary; Dr. Edwin H. Brigham, Boston, Librarian.

Dr. Franklin K. Paddock, of Pittsfield, was chosen Orator, and Dr. Robert Amory, of Boston, Anniversary Chairman for the next annual meeting.

The President introduced the President-elect, who made a brief and fitting response.

THE NEXT MEETING.

It was voted that the next annual meeting be held in Boston on the second Wednesday in June, 1885.

APPOINTMENT OF COMMITTEES.

The President nominated, and the following were appointed to constitute the standing committees: —

Of Arrangements. — C. E. Wing, A. T. Cabot, H. C. Haven, C. H. Williams, J. W. Elliot, F. H. Hooper.

On Publications. — G. C. Shattuck, R. M. Hodges, B. E. Cotting.

On Resignations. — J. Ayer, F. Minot, D. W. Cheever.

On Finances. — W. W. Wellington, B. S. Shaw, E. G. Cutler.

To Procure Scientific Papers. — C. W. Swan, G. S. Stebbins, J. R. Chadwick, R. H. Fitz, H. P. Walcott.

On Ethics and Discipline. — G. J. Townsend, G. E. Francis, A. H. Johnson, C. Howe, F. C. Shattuck.

On Medical Diplomas. — W. L. Richardson, A. H. Cowdrey, E. J. Forster.

PETITION FOR A NEW DISTRICT SOCIETY.

A petition was presented from several physicians residing in certain towns in the Norfolk District, and from Hingham, in the Plymouth District, requesting that they might be allowed to form a society to be called the Norfolk South District Medical Society. The petition was referred to Drs. Hodges, C. E. Stedman, and Spooner as a committee to report thereon at the next meeting.

AMENDMENT OF BY-LAWS. ELIGIBILITY OF WOMEN.

As was anticipated the most animated part of the meeting was the debate on the amendment to By-law I., making women eligible as candidates for Fellowship in the Society. The debate was opened by Dr. Bowditch, who, with Dr. Wyman, constituted the committee from the adjourned meeting of the Society, held during the afternoon, to present to the Council for its concurrent action the following: —

Voted, That the first four lines of By-law I. be stricken out, and the following be put in their place, namely, —

"Candidates for admission into the Massachusetts Medical Society may be either male or female, and every candidate must, by proper credentials and examination, satisfy the Censors of said Society that he possesses the following qualifications for Fellowship."

The adoption of this amendment was strongly advocated by Drs. Bowditch, Wyman, Bronson, and H. P. Bowditch, and vigorously opposed by Drs. Shattuck, Dwight, Warren, Minot, Reynolds, and Harvey. On motion of DR. HODGDON the vote was taken by ayes and nays. The amendment was carried by sixty-three in the affirmative to forty-seven in the negative.

The vote by districts was as follows: —

	Ayes.	Nays.		Ayes.	Nays.
Barnstable	1	0.	Middlesex South	17	1.
Berkshire	1	0.	Middlesex East	2	0.
Bristol North	2	0.	Norfolk	9	5.
Bristol South	2	3.	Plymouth	5	0.
Essex North	1	1.	Suffolk	11	27.
Essex South	3	4.	Worcester	8	2.
Franklin	0	0.	Worcester North	0	3.
Hampden	1	0.		—	—
Hampshire	0	1.	Total	63	47.
Middlesex North	0	0.			

Adjournment was voted at 9.20 P. M.

— The New York State Pharmaceutical Association held a convention at the College of Pharmacy last week, and after the election of officers the names of ten delegates were selected to be sent to the Governor, who will appoint five of the list on the State Board of Pharmacy.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. W. SWAN, M. D., SECRETARY.

DECEMBER 8, 1883.

A CASE OF RENAL ABSCESS.

DR. C. ELLERY STEDMAN read the case.

Mrs. B. M., aged twenty-two, was admitted to the Nervous and Renal Department of the City Hospital, November 10, 1883. Dr. Webber asked Dr. Stedman to see her, and as the latter thought he found signs of inflammatory action in the pelvis the patient was transferred to his care. She was very pale, feeble, and near her end, the eyeballs rolled up, and the features pinched. She was in no condition to bear questioning, but the following history was elicited: Of her family antecedents little could be learned. Her catamenia have been regular, lasting eight days, of which the first two were painful. She used twelve napkins. Eight months ago she miscarried at the third month. She was last unwell from the 17th to the 20th of May last inclusive, and considers herself six months advanced in pregnancy. For months has had leucorrhœa. For eighteen months she reports she has had inflammation of the bladder. Whether this is the name she gives to her malady or is the diagnosis of a physician is not recorded. During the last six weeks there has been sharp paroxysmal pain in the lower part of the left back, but she dates the commencement of her present trouble at about twelve days ago, since which time she has been in bed. At that period there began sudden sharp pain in the left lumbar region, radiating downwards toward the bladder; this pain has been constant, sharp, and worse on movement, micturition, and defecation, — somewhat relieved by drawing up her legs, — located specially on the left side, but also general in the abdomen. From the first there has been vomiting of yellow matter, frequent both on an empty stomach and after eating and drinking. There is no appetite, and the bowels are constipated; a movement was had by enema four days ago, but caused the patient great pain. Passing urine gives her so much pain that she voluntarily retains it, acute distress preceding and following the act. The urine on the 11th was cloudy, contained one third per cent. albumen, and had a sediment of normal blood, a large amount of pus, and triple phosphate crystals. She had never passed gravel or stone. There are now no chills, headache, or delirium. Temperature when admitted 10th November was 100.5° F., on the 13th 99° F., and the pulse 130, regular and weak. The tongue dry and cracked, with a brown coat. The heart gives out a loud murmur over the pulmonary orifice, and is a little enlarged, perhaps, to the left. The abdomen is distended, and universally, though not excessively, tender. In the hypogastrium, reaching to within two inches of the umbilicus, is a tumor with well-defined border, extending on the right into the lumbar region; this tumor is felt to change its shape; no fœtal heart is heard; above the tumor the abdomen is resonant. The areolæ are dark, and there is milk in the breasts. A dark line runs from pubes to umbilicus. In the left loin, in the neighborhood of the spleen, is a feeling of resistance, over which is resonance. The patient lies with knees drawn up, and features pinched, complaining of pain in the

back and tenderness over lower end of spine. The next day the record says that she vomited little during the night, but required several subcutaneous injections of one fourth of a grain of morphia. During the next three days vomiting increased in frequency; nutrient enemata were either not retained or came away little if at all changed. There was no delirium, and she died at ten minutes past ten o'clock P. M. of the 17th November.

Dr. Gannett made the autopsy thirty-six hours after death. Nothing of especial interest is recorded till the left kidney was reached. This organ was represented by a lobulated, sacculated mass measuring twenty-four by fourteen centimetres. Its form was a series of sacs or pouches about the size of a peach, and contained a thick, greenish-yellow, offensive pus. No renal substance remained except a thin layer over the lower border, perhaps five millimetres in thickness. The ureter on this side was dilated throughout to the size of the forefinger, its mucous membrane somewhat injected, reddened, and covered with a layer of pus. The right kidney was of usual size, density, and color, the capsule easily detached, leaving a smooth surface; on section the surface showed a uniform dark-red color, in which the distinctions of various sections could be made out. The right ureter was of usual size throughout. The liver was slightly enlarged, of usual color and density. The bladder was empty and contracted, containing a small amount of pus. The mucous membrane about the trigonum thickened, reddened, velvety, in many places of a reddish-blue color. The uterus contained a fœtus with the usual appearances in the sixth month of pregnancy.

The diagnosis of this case was not assured. The history of a cystitis made the appearance of pus and blood in the urine seem natural. There was no distinct tumor in the left loin, only pain and a sense of resistance to the touch, and resonance existed, as the colon superimposed would demand. The choice lay between perinephritic abscess or pyelo-nephritis, the latter being correct. An interesting case of the former disease, with suppurating kidney, was published by Dr. Lyman in the *Boston Medical and Surgical Journal*, cv., 21. This, too, was made interesting by its complication with early pregnancy; there was a tumor in the right renal region; the urine was alkaline, one fourth per cent. albumen, much pus. The tumor was discharged of pus by several operations, but the patient failed, died, and no autopsy could be had. The case resembled that now reported in several respects, but at no time since our patient was seen did operative interference seem proper.

There was history of cystitis for eighteen months, but who gave the name to the affection is not known. From Dr. Gannett's report of the autopsy it would appear that hydronephrosis had existed, as shown by the greatly dilated ureter, which may have been dammed at its entrance to the bladder by inflammation of that viscus; or hydronephrosis may have been congenital, or acquired, not recording symptoms, but waiting for some action like pregnancy to be set up and close the ureter. Says Roberts: "Simple stagnation of the urine (like decomposition) from an obstruction in the ureter usually causes only dilatation [hydronephrosis]; but if it occur suddenly the pressure of the dammed-up urine may excite acute pyelitis. Severer inflammatory changes occur if the stagnant urine becomes decomposed and its urea converted into carbonate of ammonia. It is probable that the intractable, generally fatal pyelitis which sometimes follows pregnancy arises in this way."

But in regard to pyelitis in pregnancy, in the time and with the means at my disposal, I have been unable to collect any examples, though doubtless many cases are scattered through medical literature.

DR. RICHARDSON inquired if there were any history of previous inflammatory trouble, such as might have bound the uterus down on the affected side.

DR. BOARDMAN quoted Ziemssen in support of the view that dilated kidney was sometimes the result of pressure of the gravid uterus upon the ureter, although the most frequent cause was there stated to be occlusion of the ureter by renal calculus, and a very common cause catarrh of the bladder extending up along the ureter. Cases were recorded which were due to perinephritic abscess, and some in which there was caries of the vertebræ, but in those cases when the pus entered from without there was no true pus cavity in the kidney.

DR. EDES thought malignant disease of the uterus a most common cause, when invading also the surrounding tissues, of compression of the ureters, and consequent hydronephrosis and atrophy of the kidneys.

DR. LYMAN said it was important that these things should be discussed with reference to the treatment, and especially with reference to an early evacuation of pus.

UMBILICAL HÆMORRHAGE.

DR. RICHARDSON reported a case of hæmophilia, which will be published. In one similar case which Dr. Richardson had seen in the Boston Lying-In Hospital, on the third day after birth, there was first epistaxis, six hours later bleeding from the mouth, then from the navel, and the child died thirty-six hours later.

DR. HODGDON said he had seen half a dozen such cases, almost uniformly fatal, with hæmorrhage from the cord and from the mouth and nose, and, in females, from the vagina. In two of the cases there were purpuric spots. The treatment was astringents and pressure over the cord, and chloride of iron internally.

DR. FIFIELD remarked that he had reported to this Society, two or three years ago, a case successfully treated by the application of plaster of Paris, first mixed with a little salt, then with water, and spooned on while setting. There was not a drop of blood lost after the application. Dr. Fifield was unable to state where he got the idea, but on reporting the case at the Boston Society for Medical Improvement some of the members reported successful treatment by the same means. He had heard a nurse describe a case which the attending physician sewed up, over and over, as a woman sews a seam, without attempting to transfix, and it succeeded. Dr. Fifield thought that the only rational way was by compression. In the case first mentioned the plaster remained on about four days. There was no tendency in that case to hæmorrhage elsewhere. The blood welled up from a pit or depression, as in Dr. Richardson's case.

DR. LYMAN said that, no doubt, these cases arise from want of coagulability of the blood, and asked if the child in the case reported presented icterus or anæmia (to which a negative answer was returned). If from thin blood the bleeding occurs, neither compression nor ligature will avail in the majority of cases; if from other or accidental causes the hæmorrhage is

arrested here as easily and by the same methods as in other parts of the body.

Dr. Richardson stated that the mother had used cream-of-tartar water, three or four tumblers daily.

Dr. Fifield remarked that a better styptic than iron was the fluid extract of hamamelis, the power of which in repressing hæmorrhage was perfectly wonderful. Two years ago he was called to New York to see a patient who had had hæmorrhage, and whom he had treated with ergotine subcutaneously, but the extract of hamamelis had subsequently had more effect than anything else tried. Dr. Fifield had recently seen cases of pulmonary hæmorrhage which had been arrested by about two doses of the hamamelis. Ergot, he thought, was too slow in its action.

Dr. Boardman said he would venture the opinion that ergot would have no effect on the now atrophied vessels of the umbilicus in Dr. Richardson's case. In the treatment of these cases it would seem to be well first to make a diagnosis, the fact being that hæmorrhage is frequent in cases of icterus neonatorum, but not so much the cause of death as that which causes the icterus. With the diagnosis of hæmophilia the methods suggested would seem to be poor treatment, except that by means of the plaster of Paris or the actual cautery, ordinary styptics having failed. As to the diagnosis, it is erroneous to regard the want of coagulability of the blood as denoting hæmophilia. From the article of Immermann, in Ziemssen, it appears that quite the reverse is true in the early stage of hæmorrhage; that the blood in bleeders is not paler in color than in healthy persons; that it maintains its coagulability for a long time during hæmorrhage; that it is not deficient in red corpuscles, but, on the contrary, "contains an unusually large amount of these [coagulable] elements."

In the present case, however, there has been no icterus, and the blood appears to have been notably non-coagulable; yet the diagnosis of hæmophilia seems to be confirmed by the subsequent appearance of spots of discoloration. Possibly, in the new-born infant there is a comparative deficiency of the coagulable elements of the blood, which fact may explain away, in these cases, the apparent contradiction of experience. Upon this point, however, he had no information.

Dr. Abbot thought the bitartrate of potash should not be left out of the account in considering the probable cause of the hæmorrhages. The continuous use of it, in considerable quantities, for some weeks, by the mother, was calculated to produce an impression on the fœtus, as was well known to be the case with certain powerful drugs, such as chloral and other sedatives, even when the mother experienced no ill effects.

Dr. Richardson said that the mother passed several large clots, as she had done in two previous deliveries.

Dr. J. Stedman referred to a case of umbilical hæmorrhage to which he was called in the night, a patient of the late Dr. Susan Dimock, who had tried a variety of remedies without avail. Dr. Stedman took a piece of fine, soft sponge, wet it and squeezed the water out, powdered the sponge with subsulphate of iron, applied this to the umbilicus, over the sponge laid a patch of lint, then a strip of adhesive plaster, and finally a bandage. The hæmorrhage ceased, and did not recur. The dressing was left on for several days. The bleeding began the day of the separation of the cord.

75

A CASE SHOWING THE EFFECTS OF HOT WATER ON PAPILLARY TUMORS OF THE BLADDER.

Dr. Baker reported the case of a patient, aged fifty, who nine months ago began to pass blood with the urine, with no pain, but a gradual increase in the hæmorrhage. He was sent for to see the patient two or three weeks ago, and examined the bladder through the dilated urethra, and found four papillary tumors of the bladder, the largest of them being of the size of a large English walnut, and pedunculated, the smallest of the size of a filbert, also pedunculated. The interior surface of the bladder was villous. It would have been a comparatively simple thing then to have removed the pedunculated tumors, but there was a good deal of cystitis, and Dr. Baker thought it would be better to open the bladder into the vagina, which was done. The tumors were let alone. Five or six quarts of hot water were injected per urethram, returning through the artificial vesico-vaginal fistula by the vagina, four times a day for several days, when the smaller of the growths, which came down towards the opening, was compressed and removed with the scissors, styptic cotton being used to control the hæmorrhage. In a week or ten days ether was administered, and through the fistula it was discovered that the growths had diminished certainly three quarters in size, so that the larger was not greater than the first joint of the thumb, and was comparatively bloodless, while the whole bladder was less congested. The work of removal was comparatively simple, and free from hæmorrhage. The inner surface of the bladder was then thoroughly curetted, the oozing being controlled by sponge and styptics. The case had gone on well since, and, so far as immediate recovery was concerned, promised well. Dr. Gannett had examined the growths, and found nothing malignant. The wall of the bladder at the site of the incision was fully or more than half an inch thick, but not especially indurated.

Recent Literature.

Chemistry: Inorganic and Organic, with Experiments. By Charles Loudon Bloxam, Professor of Chemistry in King's College, London, etc. From the Fifth and Revised English edition. With two hundred and ninety-two Illustrations. Philadelphia: Henry C. Lea's Son & Co. 1883.

Professor Bloxam's book is, in most respects, a very satisfactory one. We know of no treatise on chemistry which contains so much practical information in the same number of pages. It contains nearly 300 illustrations of judiciously selected experiments, which add much to the value of the work as a text-book. Such matter as would be comparatively unimportant to the majority of students, for example, the chemistry of rare elements and compounds, has been printed in smaller type, so that the book can be readily adapted not only to the needs of those who desire a tolerably complete course of chemistry, but also, by the omission of the smaller type, to the needs of those who desire only a general knowledge of the subject without going into all the details.

The table of contents is deserving of mention. It covers seventeen pages and is, in fact, a complete abstract of the whole subject, and may be usefully employed by the student in reviewing the book.

We notice with pleasure that in the present edition some changes have been made in the theoretical portion, to bring the book more into harmony with modern views on this subject.

Professor Bloxam still adheres in general to the English weights and measures and to the Fahrenheit thermometric degrees. We hope to see a change in this respect in subsequent editions.

We take pleasure in recommending this work both as a satisfactory text-book, and as a useful book of reference for those who desire such a book but do not feel able to own any of the more expensive treatises and dictionaries.

Medical and Surgical Journal.

THURSDAY, JUNE 19, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

THE MASSACHUSETTS MEDICAL SOCIETY AND WOMEN.

IN the other columns of this issue a full report of the late meetings of the Massachusetts Medical Society and of its Councilors will be found. The reunion of the Society was fully as successful and agreeable as usual. The only unusual feature, the vote by the Society and the Councilors that women be admitted to examination by its Censors, we were merely able to announce with but little comment last week, nor are we quite sure that it is worth while to do more than that even now. The time for argument is gone by, and there are no new ones on either side to be adduced.

There are, however, a few things which should be said before the matter becomes past history, though some of them be repetitions. At the meeting of the Society 332 members out of 1529 were present, of whom 209 voted in favor of admitting women and 123 against their admission. At the Councilor's meeting, 110 out of 172 Councilors voting, sixty-three voted in favor of admission and forty-seven against. It is evident from this that the organization is not moved to its inmost depths by the question. The result would seem to represent the favor shown to the persistent suitor. A comparatively small number of radicals by nature, of ardent enthusiasts who persuaded themselves that this cause was synonymous with abstract justice, and of clamorous agitators whose restlessness is now free for something else, were pretty sure sooner or later to find themselves in possession of the field at least long enough for their object; but this moment came sooner than might have been expected owing to the introduction of another element of discussion, namely, the right of the Society to change its own By-laws.

Two years ago the President of the Society ruled at one of these adjourned meetings, at which it was hoped to secure a vote favorable to the admission of women, that the initiative of new business or of any change in By-laws must take place in the Council. This ruling was at the time sustained by the members present by a small majority, but the same ruling was voted down this year vigorously, and this ruling has probably had much to do with the vote to admit women at the present time. What the real sentiment of the Society is upon that subject is not known, and is now of little consequence; but there is still in Massachusetts enough of that spirit which, in England, sent Strafford to the scaffold, and here, whilst encouraging Ann Hutchinson's Antinomian pranks, put John Winthrop in Coventry. The idea of the representatives being greater than their constituency, of the part controlling the whole, of the stream rising higher than its source, was thoroughly distasteful, and aroused a feeling which a plentiful use of such expressions as usurpation, oligarchy, and tyranny served to foment still further, a feeling which should not be confounded with a recognition of the justice, the wisdom, or the necessity of encouraging the practice of medicine by women. We are not undertaking the defense of the parliamentary rulings of the Society's presiding officers, but we do not hesitate to say that there is nothing for the Society to be proud of in the management of these adjourned meetings. If the By-laws are insufficient or unsatisfactory a usual and dignified method should be provided for changing them. If the Councilors do not represent the districts it is easy to elect others by fair, open, and legitimate methods. The Council is unquestionably better adapted for the origination and transaction of business than the Society, which is unwieldy, meets at long intervals, and then only for a short time. The meeting on the afternoon of June 10th manifested sufficiently clearly the drawbacks inherent to the transaction of serious and important business by the Society where the occupation of a certain number seemed to be to vociferate "Question!" "Question!" Whatever may be said of the President's parliamentary law his good nature was very praiseworthy, notwithstanding which it seemed at one time as though his office would be voted abolished. Now that the claims of women are satisfied would it not be well for the Society and its Council to improve this moment of tranquillity, and to adopt a manual of parliamentary procedure, and to revise its By-laws? Let the Society understand distinctly where, when, and how its business is to be transacted. As things are at present, we believe some of those who were most active in promoting the precedent set at the last meeting will be among the first to regret their action.

The question of the admission of women to the Massachusetts Medical Society is settled; that of the wisdom or profit of their attempting the practice of medicine, save in very exceptional cases or under very exceptional circumstances, is entirely open. We shall say a few words and then take leave of it, we hope,

for some time to come. We have seen no reason to change the views consistently held by this journal as to the fitness of women to practice medicine and as to the wisdom of encouraging them to do so. We are aware that we are not on the *popular* side of this question, that our views are called ungenerous by those who believe there must be a selfish motive, and narrow by those with whom novelty is synonymous with wisdom. But we dislike demagogism, whether in politics, in society, or in the professions, and do not think improvements necessarily result from change. We believe that women in this particular community are already aided and abetted in too many foolish fads and fancies. There is too much bad piano playing and too little good cooking and sewing taught them. They, more than men, are too much encouraged already to *attempt* uncommon things rather than to find an interest and profit in doing ordinary things thoroughly well. In regard to this particular fad of encouraging them to practice medicine, we know that some of those who have been in favor of it, and have even now voted to admit women to examination by the Massachusetts Medical Society, but who are candid, acknowledge that their experience derived from consultations with our best female practitioners, and from cases sent to such for treatment, tends to convince them it is a mistaken movement. If the sum total of human happiness can be increased by the pursuit by women of what have hitherto been regarded as virile occupations so much the better, but both theory and practice lead us to believe it as little in regard to medicine as to law, theology, or politics. No action of medical societies or of legislatures can alter the male and female physiology, and the experience of ages is the best index of the mental, moral, and physical fitness of each sex for the profitable exercise of certain functions. If we desire to prove these problems over again for ourselves in this age and community there will undoubtedly be a limit to the amount of harm which will result, and it may keep us out of worse mischief.

THE IMPORTANCE OF A KNOWLEDGE OF THE PHYSICAL CHARACTERS OF DRUGS.

Among the wants which the average young man feels in entering upon the practice of his profession is a practical familiarity with the physical properties of the drugs which he prescribes. In former days when the medical student spent some time as an assistant to a physician, especially when the dispensing of drugs was a part of the doctor's and more particularly of his assistant's duty, there was opportunity to become habituated to the taste, odor, and appearance of medicines. But many young practitioners of the present day, while tolerably familiar with the common therapeutical action of remedies, and possibly even having given some attention to physiological experiments on the action of drugs upon the nervous, circulatory, and other systems of the body, are yet liable in the early part of their practice to mortifying errors of tact and judgment in their selection of remedies, which could have been avoided by a better knowledge of the physical properties of the instruments they use. Outright violations of the principles of pharmacal compatibility are, perhaps, not so common as the choice of remedies and combinations, which, while therapeutically correct, and even pharmaceutically not incompatible, yet in taste and looks offend unnecessarily the senses of the patient. "Elegant preparations" are freely offered by the manufacturing pharmacists, and physicians often resort to them chiefly because they themselves lack either the time or the knowledge requisite to make up palatable prescriptions of their own. Undoubtedly many practitioners owe their success largely to a study of what may be called the æsthetics of prescribing.

The foregoing remarks have been suggested by an exhibit, which we noted with pleasure, at the recent meeting of our State Medical Society. In the museum of the new building of the Harvard Medical School there are a series of alcoves devoted to a full, methodical, and exceedingly valuable display of the principal drugs of the Pharmacopœia, arranged by the lecturer on this department in the School. The first alcoves are devoted to the drugs of organic (animal and vegetable) origin. These are arranged in alphabetical order of the crude drugs. Accompanying each specimen is a photograph (and many of the photographs are of great artistic excellence) of the growing plant. The pharmacopœal, botanical, and common names are all written upon the descriptive card. The specimen generally includes the part of the plant used in medicine, bark, root, leaf, etc., and also the powdered crude drug. Next come the pharmaceutical derivatives, tinctures, extracts, etc., in due order. The alkaloids are also displayed, each in connection with its constituent drug. An important feature of the exhibit is the quantitative assays of the drugs. For instance, under cinchona we find, besides specimens of each of the different barks, a bottle containing exactly one hundred grammes of a bark of standard purity and strength. Next this is placed a bottle containing the amount of quinine assayed from the particular specimen of bark. Then follow the other alkaloids derived from an equal quantity of the same specimen. Under opium the relative amounts of the various alkaloids and of meconic acid contained in one hundred grammes of the drug are represented in an especially striking manner.

After the organic come the inorganic drugs arranged in the same methodical way. All this, admirable as it is, appeals simply to the eye of the student, and we were glad to find that provision was made elsewhere for giving him the further knowledge which is so needful. In cases placed about the reading-room upon the lower floor of the building were specimens of all the common drugs, accessible at all times to the senses of touch, smell, and taste. Here, as readily as behind the counter of a pharmacy, might one learn what was needful to know of the physical characteristics of drugs. Such knowledge, it is to be hoped, will soon be afforded every medical student as a very important part of his professional outfit.

MEDICAL NOTES.

— The heredity record on 132 cases of cancer under treatment at the Middlesex Hospital during the year 1882 was as follows: In thirty-four cases of uterine cancer there was a history of previous malignant disease in eight families, or in 23.7 per cent.; in forty-one cases of breast-cancer, in ten families, or in 24.3 per cent.; in twenty-eight cases of cancer of the tongue, mouth, and lip, in one family, or in 3.5 per cent.; whilst in eighteen miscellaneous cancers, including ten of the rectum, no history of any previous malignant disease could be obtained. Thus, of the whole 121 cases, there was a history of previous malignant disease in nineteen families, or in 15.7 per cent.

— In an article by Dr. Reichel, of Breslau, copied into the *St. Louis Courier of Medicine* from the *Berlin. klin. Woch.*, he describes a case of general erythema caused by sublimate dressing. A man had been operated on for relief of genu valgum; the leg from foot to pubes was enveloped in sublimate gauze. On the ninth day burning and itching of the limb necessitated the removal of the gauze. The leg was œdematous, and covered with a papulo-vesicular eczema. A general erythema was now developed; the whole body, except the face and neck, was thickly covered with small red spots. The general health was good; no salivation; temperature raised. Salicylic dressing was substituted, and on same day temperature became normal; and in four days after the whole rash was gone.

— Dr. Lawson Tait, of Birmingham, England, is about to visit this continent for the purpose of giving an address on abdominal surgery before the Canada Medical Association at Montreal, August 25th.

— The correspondents of the *Medical Press and Circular* are very generally by the ears over the question "What is medical advertising?" which was raised by one signing himself "Anti-humbug" some weeks ago. Several contributions upon the subject have appeared, and a good deal of covert sarcasm has been aimed at various leaders of the profession. The issuing of bulletins by the attending physician whenever any noble peer has sneezed unduly or a member of the royal family has the stomach ache is justly made an especial object of ridicule. The attempts of some writers to establish a distinction between legitimate and illegitimate advertising are rather laughable. But meantime it certainly does remain a difficult point to determine exactly where the dividing line lies between self-respect and self-exaltation.

— A correspondent of *Science* (June 6th) describes a tailed child which was recently born in Louisville, Ky. A visit was made by a party of four, which included a prominent physician. The writer says: —

"We found a female negro child, eight weeks old, normally formed in all respects, except that slightly to the left of the median line, and about an inch above the lower end of the spinal column, is a fleshy, pedunculated protuberance about two and one half inches long. At the base it measures one and one quarter inches in circumference. A quarter of an inch from the base it is somewhat larger, and from that it tapers gradually to a small blunt point. It closely resembles a pig's tail in shape, but shows no signs of bone or cartilage. There seems to be a slight mole-like pro uberance at the point of attachment. The appendage has grown in length about a quarter of an inch since the birth of the child.

"The mother, Lucy Clark, is a quadroon, seventeen years old, and the father a negro of twenty, both normally formed.

"In Darwin's Descent of Man, vol. i., p. 28, he speaks of a similar case, and refers to an article in *Revue des Cours Scientifiques*, 1867–68, p. 625. A more complete article is that by Dr. Max Bartels, in *Archiv für Anthropologie* for 1880. He describes twenty-one cases of persons born with tails, most of them being fleshy protuberances like the one just described."

— We learn from the *London Medical Times* that in a paper lately read before the Académie de Médicine Dr. Marc Sée stated that he has deduced the following conclusions from his anatomical measurements: "(1.) In the normal state the united calibres of the two bronchi are equal to the calibre of the trachea, and I may add that, according to a few measurements which I have made, the united calibres of the bronchial subdivisions equal the calibre of the bronchus from which they originate. The respiratory passages, therefore, represent a cylinder and not a cone. (2.) In the pathological condition the equilibrium between the capacity of the trachea and bronchi may be destroyed, either in favor of the bronchi, as in chronic tuberculosis, or to the advantage of the trachea, as in emphysema."

— The *Annales des Maladies de l' Oreille, du Larynx et des Organes Connexes*, founded in 1874 by Isambert and Krishaber, deceased, and Ladreit de Lacharrière, is to be made, under the direction of the surviving editor, an international journal, and is to be published in both French and English.

The direction and publication will remain in Paris, and the editors selected for the laryngological and otological departments respectively are, in England, Morell Mackenzie and Woakes, in Belgium, Capart and Ch. Delstauche, and in America, J. Solis Cohen and Clarence J. Blake.

— Dr. William Goodell, of Philadelphia, recommends the following prescription in pruritus vulvæ: Carbolic acid, one drachm; morphine sulphate, ten grains; boracic acid, two drachms; vaseline, two ounces. Also pat the parts with a sponge soaked in boiling-hot water.

— The house No. 421 Shawmut Avenue in this city, which has been secured for the Home for Aged Couples, was formally opened last week in the presence of a distinguished company and with agreeable festivities.

— A correspondent of the *British Medical Journal* calls attention to the following prescription, which was made up for a lady, and which gave rise to alarming results on account of the solubility of strychnia in chloroform and the insolubility of the latter in water: —

℞. Liquoris strychniæ ʒi.; spiritûs chloroformi ʒiij.; aquæ ad ℥iss. M. A teaspoonful to be taken three times a day in water. "Upon taking the final dose, which tasted unusually hot," adds the writer, "my patient was seized with spasmodic contraction of the extensors of the feet and legs, the limbs being forcibly projected under the table at which she sat. These symptoms soon passed off, but were alarming for the time. On my being shown the bottle which had contained the medicine a drop or two of water was seen remaining in it, and beneath this a globule of chloroform, which proved to be highly charged with strychnia.

"The prescription was faulty. Chloroform is a powerful solvent of sulphate of strychnia, and itself is not very soluble in water. More was ordered than the menstruum could take up; the surplus, therefore, appropriated to itself a large amount of the salt and fell with it to the bottom of the bottle."

— Governor Robinson at a meeting of the Executive Council last week renominated twenty-five medical examiners in various parts of the State, among them Medical Examiners Draper and Harris, of Boston.

— In a recent article in *Macmillan's* on a great Town-Hospital, intended to inform the general public on hospital patients and methods, the writer (a trained nurse?) speaks of the carbolic spray being played upon the wound of a patient, and remarks exegetically for the benefit of the reader that this is done for the purpose of keeping the wound warm!

NEW YORK.

— At a meeting of the Society of Medical Jurisprudence and State Medicine, held at the Academy of Medicine June 11th, a paper by Prof. J. G. Kiernan, of Chicago (formerly of New York), entitled Some Suggestions Concerning the Dwight Insurance Case, was read by H. W. Sackett, Esq. In it the writer said "The decision in the Dwight case was fully warranted, even allowing that the deceased was a suicide. Supposing Colonel Dwight was insane, and with an insane idea of smartness had committed suicide with a vague notion of making money for his friends, would that act vitiate his policy? Under the laws of Iowa it would not, and legally the policy could not be declared void." The question was stated to be simply one of a contract with an insane person, and not of fraud. The paper was discussed by Drs. Spitzka and Harwood.

— An informal opening of the "Health Home" at Coney Island, organized under the auspices of the Children's Aid Society, took place on the 11th of June. The party of ladies and gentlemen who attended it first visited the "Summer Home" at Bath, L. I., which was the gift of Mr. A. B. Stone, and which receives some four thousand poor children during the season. They then went to the new sanitarium on the western part of Coney Island. It is in an excellent situation, with a superb ocean view, and the building, which is picturesque and convenient, with piazzas a hundred feet in length, has been presented to the Society by Mr. D. Willis James. There will be a resident physician, and in addition to the large numbers going to the place for the day, parties of sick and convalescent children, with their mothers, will be kept for a week or more at a time.

Miscellany.

THE PRINCIPLES OF MODERN THERAPEUSIS.

From an introductory lecture by Prof. H. C. Wood, published in the *Philadelphia Medical Times* (May 31st), we make the following extracts:—

"The modern physiological school of therapeutics starts with the understanding that there is at present no known law of therapeutics, — unless it is that of antagonisms — by which is meant that it is possible, when a mass of living protoplasm is depressed by some agent, to overcome the depression by a second agent, which is stimulant to the protoplasm; or, in other words, that whilst some agencies increase the molecular movements of the protoplasm, others lessen them, and that it is at least theoretically possible to balance more or less perfectly one of these forces against the other.

"The great therapeutic departure of the last decade is the general abandonment of the statistical method of therapeutic research, and the substitution therefor of the so-called physiological method. According to the latter plan, disease is to be first studied in its natural history, so as to determine whether it has a definite course which cannot be arrested, and, if so, what is the progress of such course; whether the natural tendency of the disease is towards recovery or towards death, and, if the former, why this tendency is sometimes not fulfilled, — that is, how death is produced in the exceptional cases. If the tendency of a disease is fatal, then the study of the possibility of arresting the disease becomes a problem of great interest.

"Having, by studies of the character just glanced at, determined what is possible and useful to be done, the therapeutist next studies the drugs and remedial agencies at command. By investigations upon man and the lower animals he endeavors to learn exactly how these drugs act upon the human system, first in health and afterwards in disease.

"When he has by these two classes of studies learned, in the first place, what he wishes to do, and, in the second place, what he has to work with, he adapts his means to his ends by reasoning not different from that which guides the chemist, the engineer, or any one dealing with difficult force-problems. . . .

"The modern scientific therapeutist, knowing what he desires to do, studies his instruments. To do this he experiments upon animals, because the modern conscience refuses to allow of human vivisection. It has been over and over again denied that we can reason from the action of drugs upon animals to their action upon man; but it is not worth while, at present and in this place, to attempt to show in detail the absurdity of such denial. The whole evidence of modern science indicates that, at least in his animal organism, man is not a mysterious creature apart from the rest of creation, but is an animal having structural and chemical relations, within and without, similar to those of other animals. . . .

"Summing up into a sentence, it may be said that

the general principles which underlie rational therapeutics are to know what can be done and what it is desirable shall be done; then to know the means at command; and, finally, to adapt the means to the end.

"At present, the therapeutist is forced to supplement this principle by a pure empiricism, on account of the imperfection of our knowledge, not so much of the action of therapeutic remedies as of the nature of disease. We have no idea as to the nature of malaria, or of its immediate action upon the human organism; how, then, can we tell in what way quinine acts as a specific against it, — a fact which we abundantly know, empirically? The best therapeutic practice of to-day is therefore a mixture of science and empiricism; but the science has enormously increased in the last twenty years, and is advancing with arithmetical progression."

MRS. HOPKINS OF HARTFORD UPON CONNECTICUT.

MR. HOPKINS, the governour of Hartford upon Connecticut, came to Boston, and brought his wife with him (a godly young woman and of special parts), who was fallen into a sad infirmity, the loss of her understanding and reason, which had been growing upon her divers years, by occasion of her giving herself wholly to reading and writing, and had written many books. Her husband, being very loving and tender of her, was loth to grieve her; but he saw his error when it was too late. For if she had attended her household affairs, and such things as belong to women, and not gone out of her way to meddle in such things as are proper for men, whose minds are stronger, &c., she had kept her wits, and might have improved them usefully and honorably in the place God had set her. He brought her to Boston and left her with her brother, one Mr. Yale, a merchant, to try what means might be had here for her. But no help could be had. — *John Winthrop's History of New England*, vol. ii., p. 265.

EXCISION OF THE RECTUM FOR CANCER.

MR. HARRISON CRIPPS recently read before the Clinical Society of London[1] the notes of three cases of cancer of the rectum in which he had excised the lower part of the bowel, the operations having been performed respectively seventeen months, eighteen months, and four years ago. In the first case, that of a man aged sixty-eight, the symptoms had existed for two years. The disease consisted of a hard, irregular mass on the posterior and right wall of the rectum, about two thirds of the circumference of the bowel involved, the disease not extending more than two and three quarters of an inch from the anus. The lower three inches of the bowel were removed with the exception of about one fourth of its circumference on the anterior wall. The patient was much troubled during his convalescence from symptoms arising from enlarged prostate, but was discharged in a satisfactory condition so far as the bowel was concerned. At the end of a twelvemonth his medical attendant wrote that he was alive and comparatively comfortable; no return of the disease could be detected, but he was unable completely to retain his fæces. Mr. Cripps had examined this patient since sending in the paper, and found that he was suffering considerably from prostatic troubles. There was some hardness in this neighborhood, but no certain symptoms of recurrence. The second case was that of a lady aged sixty. The disease extended all round the bowel on the anterior wall, nearly as high as four inches. Mr. Cripps did not regard the case, from its extent, as a very favorable one for operation, but at the wish of the patient undertook its removal. The bowel had to be dissected for two inches from the peritonæum. The patient made a very satisfactory recovery. She suffered much from contraction, but there was no recurrence for more than a year; the disease then recommenced. The last case was that of a lady, aged forty, who was recommended to the author by Dr. Matthews Duncan. The disease consisted of a hard, ulcerated mass, involving one half the circumference of the bowel to a height of two inches, and filling the ischio-rectal fossa. The disease was removed in July, 1880, and proved, under the microscope, to be a typical example of adenoid cancer. The patient has been frequently examined since. She has completely regained her old strength and health, has no pain or discomfort whatever, and remains, after nearly four years, perfectly free from any symptom of recurrence.

The remarkably favorable results secured by Mr. Cripps were not in accord with those attained by a number of the speakers who took part in the discussion. The president, Sir Andrew Clark, in summing up, said that the discussion had shown that whilst excision of the rectum served to give relief for a time it did not tend to prolong life. He mentioned one case in which he had diagnosticated cancer six years before the patient's death. He considered that the limit of eighteen months, so frequently laid down in books, was not in accordance with general experience.

QUICK TIME ON SNOW-SHOES.

SOME question having been raised, says *Science*, in relation to the distance traveled by the Lapps of Baron Nordenskiöld's party in their excursion into central Greenland Mr. Oscar Dickson arranged for a series of races on *skidor* ("snow-shoes") at Quickjock in Lapland. The distance which they claimed to have traveled over the Greenland ice was two hundred and thirty kilometres, going and returning in fifty-seven hours. For this reason the courses were arranged so as to have a total length of two hundred and twenty-seven kilometres. The races took place on the 3d of April last, and were spread over six days. The following results were obtained: —

The first prize, three hundred and fifty francs, was gained by Pavo Lars Tuorda, one of those who had visited Greenland with Nordenskiöld, and who traveled over the above-mentioned distance, equivalent to one hundred and forty-one miles, in twenty-one hours twenty-two minutes, including all stoppages. The second prize was gained by Pehr Olof Ländta, who came in half a minute later. The third and fourth prizes were awarded for the times of twenty-one hours thirty-three and a half minutes and twenty-one hours and fifty-six minutes, respectively. Four others received a gratuity of thirty-five francs for having covered the dis-

tance in less than twenty-six hours. All arrived in good condition, unexhausted, and took part in the festivities which followed the races. Many of them had also traveled from seventy to a hundred kilometres before the race to get to the point where the course began. It will be observed that the result completely confirms the claims of the Lapps on their journey in Greenland as far as a parallel performance can do so.

REPORTED MORTALITY FOR THE WEEK ENDING JUNE 7, 1884.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 2389 (no reports from St. Louis, New Orleans, Buffalo, and Providence): under five years of age, 906; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 394, consumption 377, lung diseases 225, diphtheria and croup 108, diarrhœal diseases 75, scarlet fever 53, measles 53, whooping-cough 29, typhoid fever 29, malarial fevers 13, puerperal fever 11, cerebro-spinal meningitis 10, erysipelas nine, small-pox four. From *measles*, New York 28, Chicago 14, Pittsburg four, Philadelphia, Brooklyn, Boston, Baltimore, District of Columbia, Fall River, and Taunton one each. From *whooping-cough*, Brooklyn eight, New York six, Philadelphia, Chicago, and Boston three each, Pittsburg two, Baltimore, District of Columbia, New Bedford, and Peabody one each. From *typhoid fever*, Philadelphia eight, Chicago five, Cincinnati three, Brooklyn, Boston, and Baltimore two each, New York, Milwaukee, New Haven, Charleston, Cambridge, Holyoke, and Wakefield one each. From *malarial fevers*, New York six, Baltimore three, Brooklyn two, Philadelphia and Chicago one each. From *puerperal fever*, Brooklyn four, Chicago three, Boston two, New York and Cincinnati one each. From *cerebro-spinal meningitis*, New York four, Philadelphia two, Milwaukee, New Haven, Fall River, and Salem one each. From *erysipelas*, Philadelphia four, New York and Boston two each, Brooklyn one. From *small-pox*, Pittsburg two, Philadelphia one.

In 100 cities and towns of Massachusetts, with an estimated population of 1,351,385 (estimated population of the State 1,955,104), the total death-rate for the week was 16.31 against 16.50 and 14.86 for the previous two weeks.

Cases reported in Boston: scarlet fever 51, diphtheria 32, typhoid fever six, and measles three; in Milwaukee, scarlet fever 15 and diphtheria seven.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending May 24th, the death-rate was 19.9. Deaths reported 3343: acute diseases of the respiratory organs (London) 261, measles 156, whooping-cough 138, scarlet fever 68, diarrhœa 46, fever 37, diphtheria 28, small-pox (London 17, Sheffield three, Liverpool two, Derby and Sunderland one each) 24. The death-rates ranged from 10.9 in Birkenhead to 28.1 in Oldham; Leicester 16.9; London 18.5; Bradford 18.9; Sheffield 19.3; Birmingham 20.6; Liverpool 21.2; Leeds 22; Nottingham 22.4; Manchester 25.1; Newcastle-on-Tyne 25.2; Blackburn 25.5. In Edinburgh 18.8; Glasgow 25.8; Dublin 23.8.

For the week ending May 24th, in the Swiss towns, there were 35 deaths from consumption, typhoid fever 19, lung diseases 18, diarrhœal diseases 18, diphtheria and croup seven, scarlet fever three, erysipelas two, whooping-cough one. The death-rates were, at Geneva 18.3; Zurich 15.8; Basle 22.6; Berne 14.4.

The meteorological record for the week ending June 7th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

[1] O., cloudy; C., clear; F., fair; G., fog; H., hazy; S., smoky; R., rain; T., threatening.

LIST OF OFFICIAL CHANGES[1] IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING JUNE 14, 1884.

AUSTIN, A. A., passed assistant surgeon, detached from U. S. S. St. Louis, ordered to Naval Rendezvous, Philadelphia.

EDGAR, T. M., passed assistant surgeon, detached from U. S. S. Wabash, ordered to U. S. S. Nantucket.

BALDWIN, L. B., passed assistant surgeon, ordered to U. S. S. Wabash.

WHITAKER, H. W., assistant surgeon, detached from Naval Rendezvous, Philadelphia, ordered for examination preliminary to promotion.

HESLER, F. A., assistant surgeon, ordered to U. S. S. Minnesota.

MEANS, V. C. B., assistant surgeon, ordered to U. S. S. Vermont.

BROWNE, T. M, medical director, to attend the International Health Exhibition at Liverpool, Eng., and delegate to International Medical Congress at Copenhagen, per steamer of July 2d.

TRYON, I. R., surgeon, to same duty with Medical Director Browne, and on completion of this duty to report for duty on U. S. S. Quinnebaug.

HUGG, J., surgeon, detached from Quinnebaug; on reporting of relief to return home and report arrival.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM JUNE 7, 1884, TO JUNE 13, 1884.

THE Army Medical Examining Board, New York City, is dissolved, to take effect June 14, 1884.

BROWN, JOS. B., lieutenant-colonel and surgeon. Upon completion of the business of the A. M. B., directed to comply with S. O. 44, current series, A. G. O., and return to New York City.

CLEMENTS, BENNETT A., major and surgeon. Directed to await orders in New York City.

KIMBALL, JAMES P., captain and assistant surgeon. Granted leave of absence for two months and fourteen days, to take effect June 14, 1884, and ordered to relieve, August 28, 1884, Captain Robert H. White, assistant surgeon, from duty at U. S. Military Academy, West Point, N. Y.

CAPTAIN WHITE, on being relieved, ordered to report in person to the commanding general, Department of California, for assignment to duty.

STERNBERG, GEORGE M., major and surgeon. Relieved from temporary duty in S. G. O., and ordered to assume the duties of attending surgeon and examiner of recruits at Baltimore, Md. S. O. 131, A. G. O., June 6, 1884.

FINLEY, J. A., captain and assistant surgeon. Relieved from duty at Fort Stockton, Texas, and assigned to duty as post surgeon at Fort Concho, Texas. Paragraph 4, S. O. 69, headquarters Department of Texas, June 2, 1884.

MIDDLETON, PASSMORE, captain and assistant surgeon. Leave of absence extended three months on surgeon's certificate of disability. Paragraph 3, S. O. 134, A. G. O., June 10, 1884.

BARNETT, RICHARDS, captain and assistant surgeon. Assigned to duty as post surgeon, Mount Vernon Barracks, Ala. Paragraph 2, S. O. 113, headquarters Department of the East, June 9, 1884.

GARDNER, EDWIN F., captain and assistant surgeon. Relieved from duty at Fort Walla Walla, Wash. Ter., and assigned to duty as post surgeon, Fort Canby, Wash. Ter. Paragraph 1, S. O. 75, headquarters Department of Columbia, June 3, 1884.

CUNINGHAM, T. A., captain and assistant surgeon. Ordered to relieve Assistant Surgeon C. B. Byrne, U. S. A., from duty at Fort Lewis, Col. Assistant Surgeon Byrne, when so relieved, ordered to proceed to Fort Gibson, I. T., and report to the post commander for duty. Paragraph 2, S. O. 112, headquarters Department of Missouri, June 4, 1884.

BANISTER, J. M., first lieutenant and assistant surgeon. Granted leave of absence for one month and seven days, to commence June 13th. S. O. 22, headquarters Division of the Atlantic, June 5, 1884.

MCCREERY, GEORGE, first lieutenant and assistant surgeon. Granted leave of absence for two months, with permission to apply to the Adjutant General of the Army for two months' extension. Paragraph 3, S. O. 56, headquarters Division of Missouri, June 5, 1884.

SIX GENERIC DRUG MODIFICATIONS.[1]

BY HENRY M. FIELD, M. D.

"I CONCLUDE, therefore, of this and other medicines, as Thucydides of the plague at Athens, no remedy could be prescribed for it, *nam quod uni profuit hoc aliis erat exitio*; there is no catholic medicine to be had, — that which helps one is pernicious to another." — ROBERT BURTON.

WHAT Virchow calls the "mystery of individuality" continually confronts the physician in the prescribing of remedies. Other mysteries may, with growing familiarity, become less obscure; skill and confidence otherwise enlarge with use and experience, but the oldest and the wisest practitioner must still confess himself frequently baffled by the mysterious modifications which the individual constitution continually introduces into the operation of his most familiar remedies. "When," observes a recent writer, "we recall only a few of the minutiæ which must be taken into account, for example, the infinitely great difference in the distribution of blood-vessels in organs, the multiform arrangement of glandular tissues in glands, the deviations in innervation of organs, the difference in size of individual nerves, and in the distribution of nerve plexuses, the variations in the gross and in the histological construction of the same muscles in different individuals, we must confess that not only is our present ignorance great, but that it will always continue."

In this connection and of what has been well called anatomical idiosyncrasy, an observation connected with the ophthalmological use of atropia affords a good illustration. Instilled into the eye in whatever quantity, employed in collyria for however long a time, atropia should exert no influence beyond its local effect, and such is the general result of its use. There is, however, rarely observed constitutional implication, and this has been traced to an anatomical peculiarity. It is not any part of the salt absorbed from the eye that affects the system, but such portion of it as was taken up by the lachrymal ducts and so conveyed to the throat and stomach. "Susceptibility, therefore, to this mode of action stands in direct ratio to the width of the tear-passages. Proof of this statement is furnished, according to R. Liebreich, by those who have impermeable tear-ducts, and whose general condition is never affected, even by the largest doses used for a long period."[2]

Such are but a few, and these the more obvious and superficial, of the conditions which determine individuality. The problem has other elements at once more controlling and recondite, not easily expressed in words, but the reality of which is recognized by every thoughtful physician. "The possibility of explanation," says Virchow, "is no test of knowledge, for we know many things empirically whose causes we cannot comprehend. No exact investigation, either anatomical or physiological, pathological or therapeutical, has ever succeeded in lifting the veil which conceals the conditions governing individual peculiarities. In all times it has been regarded as the peculiar prerogative of exceptionally gifted spirits or of great experience to possess that subtle insight which enables one to recognize, even approximately, the specific character of the individual."

What may be called *indicia* of idiosyncrasy are greatly to be desired; such as past experience has possessed us of are at best few and uncertain. Jonathan Hutchinson has remarked that all persons of dark complexion bear mercurial treatment well and require larger doses than those who are fair; nay, more, that individuals of the former class may enjoy better health while taking mercury, "and are not infrequently much and permanently benefited by a long course." On the other hand, dark-complexioned people do not bear tonics well, they are apt not to be helped by sea-air; "the need of purgatives is greater in them." In those of fair complexion belladonna is observed to exert its highest power. Just as we know that acne is most liable to appear in individuals of a certain quality of skin and at a certain period of life, so we may expect that the iodides and bromides, pushed a little under these circumstances, will produce characteristic cutaneous eruptions. Finally, we know — and a most unhappy piece of knowledge it often is — that it is just in the constitution which most needs the staying and tranquilizing influence of opium, that is, in the hyperæsthetic and neuralgic female, that its anodyne and hypnotic virtues are most apt to fail us, while in such systems it may play the rôle of a veritable fiend.

The hope that what experience did not impart, an *a priori* method of studying and reasoning might supply, naturally a product of the deductive philosophy of an earlier age, was doubtless directly concerned in the determination of temperaments by the ancients, an effort towards specific knowledge in the direction of individualism. And it must be admitted, though their terms be far from scientific, we all of us still find them very convenient. Indeed, the attempt at classification in individuality has not been wholly resigned to the contemporaries and successors of Galen and Paracelsus; and it is hardly more than twenty years ago that so prominent a practitioner as Dr. Laycock wrote quite exhaustively upon the subject. It is doubtful, however, if we are made any better off for his six temperaments than for the four we had previously. Such studies have their value in our scientific age, when the minds of men are so generally given to the pursuit of the demonstrable and of that alone which is capable of strict definition. Once that the disease were determined it is not at all sure that the practitioner trained in the school of Laennec would treat a pneumonia better than would he who was taught in the school of Hippocrates; and quite likely the latter would be nearer right in prognosis. Just here is suggested a danger that we may lose much as medicine makes its transition from art to science. The "gifted spirits" of Virchow are not the anatomists or the pathologists, they are not of necessity the clinicians, full men though they may be, and exact in the practical knowledge of hospitals and schools; they are rather those who, some way, find the largest success in the treatment of disease, whose wide range of therapeutic resources is both intuitive and acquired, whose sense, aided or not by instruments of precision, looks deeper and sees farther than that of other men, who wrest secrets from nature, and, in the language of the French proverb, are concerned "not with sicknesses but with the sick." It was a good pathologist who gave three good reasons why his patient could not get well, but it was a better doctor who, against all reason, rescued him.

[1] Annual Address delivered before the Middlesex South District Medical Society, at Cambridge, April 16, 1884. Published by vote of the Society.

[2] Lewin.

The occasional extraordinary behavior of quinine affords a good illustration of what we mean by idiosyncrasy. We do not now refer to what has been called quinine poisoning, a condition which may accrue from quite small doses, and which is variously characterized by determination of blood to the head, œdema of the face, itching of cutaneous surfaces, great excitement, and even delirium, followed by extensive desquamation. This pertains to individuality, but it has been well described in certain cases published in the journals and the books. But in the exceptional condition now in mind quinine acts in a way the exact opposite of its otherwise observed and characteristic action. Intrinsically a corroborant, a dynaphor, as the French conveniently call it, that is, a force-begetting, force-imparting remedy, it now acts to prostrate and overwhelm. The patient complains of increased weariness; there is trembling of the hands, unsteadiness of gait, a feeling of great weakness in the legs, more or less complete, and perhaps extreme, suffusion of perspiration, with conjoined depression of spirits, melancholy, impaired mental power, etc., etc. Such syndroma, which, in another and otherwise caused, quinia should be calculated directly to antagonize, to relieve or lift altogether, follow so soon after the ingestion of the remedy, and are so surely aggravated by successive doses, that soon, it may well be, both physician and patient are brought to suspect the source of the mischief.[1]

A somewhat prevalent misconception or inadequate knowledge among the profession upon the general subject of quinia incompatibility is well illustrated by remarks of Dr. David Young, of Rome, in a recent article contributed to the *Practitioner*. He speaks of a "belief on the part of many patients, a belief also shared in by not a few eminent physicians, that they cannot take quinine in any form or dose; and I have met with such patients in Italy," continues the doctor, "who told me they were advised by their own medical men at home to assure any physician whom they might have occasion to consult that they could not take quinine." He suspects that there is a "physiological reason" for this fact of intolerance, and that "ere long investigation will discover what this reason is," and proceeds to remark upon the "curious fact that the same wide-spread belief exists in regard to the use of iron." The illustration is an unfortunate one; the analogy cannot be maintained, for the fact is, as I conceive it, that iron intolerance, when presented, is, indeed, almost invariably due to a "physiological reason," a temporary physiological condition which it is for the physician to estimate and remove; for example, a state of pyrexia, of biliousness, a failure in selection of the right pharmaceutical preparation, or in determination of the right dose; whereas quinine intolerance, when it exists, is an established fact, and has its source in the very nature of the man, or, in a word, is what we have recognized it to be, a phenomenon of idiosyncrasy.

[1] I am glad to find, in Hutchinson's Pedigree of Disease, the recognition of a principle which I learned, some time ago, to apply in my own practice, especially in respect of the present material, but which I have not seen stated elsewhere. "It by no means follows," he remarks, "that because a patient has an idiosyncrasy against some drug we ought wholly to abstain from its use. Rather this susceptibility proves, in the majority of cases, that in him minute doses will effect the cure as efficiently as larger ones in others." He instances tertiary syphilitic ulceration cured by one third to one half grain doses iodide potassium. I have applied this method in malarial seizures, and accomplished full medicinal purpose with one half to two grains quinine, and at the same time avoided unfortunate physiological impression.

Iodine, as misdirected by individual constitution, is a not infrequent occasion of surprise, annoyance, or aggravation. For this we may perhaps be partly prepared when we consider the wonderful power of this drug to penerate the system, the wonderful speed of its circuit, and the extraordinary range of its possible elimination; a threefold quality which may well bring it into collision with a lurking idiosyncrasy. Ingested into the stomach as metalloid or salt, the promptitude with which it may be rendered in the renal flux or returned in the saliva is familiar to every physiologist. I have, at least on two occasions, had patients to whom I had made application of a few drops tincture iodine, upon absorbent cotton by shielded applicator to the interior of the uterus, declare that iodine had been used because it was tasted in the mouth. Hardly more than three minutes — and surely not five — had elapsed before this impression was made. Here the area of absorption must have been confined to the endometrium, none of the remedy having come in contact with any part of the vaginal wall.

The inherent power which every active remedy has to exert desirable and undesirable properties at the same time is also well illustrated by iodine as modified by individualism. Lewin's experience is here to the point: "Given for the purpose of producing a diminution in volume of hyperplastic glands, as the cervical lymphatic or the thyroid, etc., it produced the desired effect and at the same time a serious atrophy of glands previously healthy, as the mammæ or testicles." Iodine, like opium, may accomplish the purpose of its exhibition, but in so malignant a way that the relief afforded costs seriously through the discomforts it imposes. This is well illustrated by the experience of a patient of mine, a young medical man, who had found in iodide of potassium a complete, and the only effectual remedy for a painful asthma. The drug, however, produced synchronously such a degree of lachrymal and nasal catarrh, such a persistent foul taste in mouth and foul odor of breath, that the victim of idiosyncrasy, after repeated unfortunate trials, gave up all treatment and resigned himself as patiently as he might to his old enemy.

Iodide is so prolific in individual constitutional disturbances that we leave the subject with reluctance, but can give space for but little further remark. The power which idiosyncrasy, indeed, may assert in this connection is well shown by Hutchinson's observation, who has repeatedly seen doses of only half a grain produce definite symptoms of poisoning in the course of a couple of days; and yet has known a patient to swallow one and a half ounces a day of the best Apothecary Hall iodide for a week together without any especial effect except the production of a degree of lassitude.

The morphology of skin eruptions, under varied constitutional iodism, presents a wide range, and may obtrude problems hard to solve. In one instance an infant was treated for small-pox by "an experienced and sagacious surgeon," and kept carefully quarantined for a month, — to present in the end only a case of iodide of potassium poisoning. A man was treated in hospital for syphilis, pretty surely killed by iodide of potassium, and then declared never to have had syphilis at all. Such experience as this is calculated to enforce the eleventh aphorism of Arnoldus, which asserts that the "wise and conservative physician never hastens to have recourse to medicine *nisi necessitate cogente*."

The misinterpretation which follows has its amusing side. In 1862 the dermatologist Bazin, of Paris, published a description of a new form of skin disease, for which he proposed the name "*hydroa*." Other observers followed with similar accounts. Later, an authority objected both to the term and to the claim of novelty, and pronounced the disease a variety of "urticaria bullosa." It was not till some time after 1870 that proof was afforded that all were alike at fault, and in "hydroa" was recognized only an extraordinary idiosyncrasic sport of iodine.[1]

One illustration more. It has been lately pointed out by a French author that the medicinal employment of the oil of turpentine may occasion a condition of the kidneys which causes the urine, on chemical examination, to simulate albuminuria. This fact is alluded to in my recent monograph on The Balsamics, and a simple device given by which the error can be set aside. In a volume of papers by Dr. Seguin of New York, — Opera Minora, — published the present year, a corresponding charge is brought against iodide of potassium as respects microscopic examination of the urine. He reports three cases attended by conditions which warrant the statement that iodide of potassium "may give rise to the formation of hyaline and epithelial casts without (there being) albuminuria or other rational symptom of Bright's disease." This, so far as I know, is the latest observed — as well as one of the most singular — freaks of idiosyncrasy in the conduct of this versatile drug.

(*To be continued.*)

SEWAGE SYSTEMS AND THE EPURATION OF SEWAGE BY IRRIGATION AND AGRICULTURE.[1]

BY HENRY J. BARNES, M. D.

DANTZIC, situated about three miles from the Baltic, on account of pollution of its harbor at the mouth of the Vistula, constructed a sewer to discharge on a sandy island having little or no soil, where the occasional tufts of grass were frequently covered with sand carried by the wind. As a result the island is now in a high state of cultivation. In some tracts the land rents to peasants at from twenty to thirty dollars per acre. The frosts of winter do not interfere with the successful operation, as the water delivered by the sewer melts the snow and ice, so that it finds its way into the ground quite as well as in summer, and without injury to the slumbering vegetation. Odessa, Breslau, and Florence also have sewage farms. M. A. Durand-Claye, from whose reports this information is derived, says that "in Germany it is admitted without question that municipal healthfulness depends upon three principles: first, the total discharge of water-closets in sewers; second, the distribution of an abundant supply of water in dwellings, and frequent flushing of drains; third, the purification of sewage by soil and vegetation."

In England there are two hundred cities and towns disposing of sewage by irrigation and agriculture. On the farms at Edinburgh are located beautiful nurseries for the children of the city. At Lochend a farm taking sewage from this city has produced $200 worth of hay per acre. The Metropolitan Sewer Company of London rents land at $100 per acre for grazing. Sixteen acres at Rugby furnish feed for fifty-four head of cattle, and at Aldershot, Branbury, Bedford, Croydon, Norwood, Warwick, and Worthing the reports in detail show an equally wonderful production from the land treated in this manner.

Leamington, with 26,000 inhabitants, spent $40,000 in chemical experiments, after which the A. B. C. Company in 1869 attempted to purify the sewage, but gave it up in 1871. It was then allowed to flow into the River Leam. A lawsuit followed, costing the city $25,000, in which it was defeated, and compelled at an expense of $7500 more to purify the river. Lord Warwick then consented to receive the sewage on his estate, the city contracting to deliver it at the highest point of the farm for a period of thirty-two years, for which Lord Warwick engages to pay $2250 annually. The sewage amounts to a little over 1,000,000 gallons per day, and is distributed over the land, which has not been leveled, by what is known as the "donkey back" system, — elevated open drains, on the sides of which is the vegetation. It has transformed the poorest parts of the farm into soil of much fertility, and financially has proved a great success. From eight to nine cuts of Italian rye grass two feet high are made each year. Celery, strawberries, and currants grow remarkably well. The beef, milk, and butter are in great demand and bring the highest prices. The laborers are in the best of health, and Lord Warwick has received numerous prizes and silver cups for one of the best kept farms in the kingdom. A more detailed account may be found in Babut du Maris' work.

The sewage farm at Croydon is surrounded by beautiful villas, it being a fashionable resort. The land which twenty years ago sold for $300 per acre is now worth from $2,000 to $5,000. There has been but one complaint of the farm during the past twelve years, and this resulted from excessive irrigation during a long period of stormy weather, when the hay could not be dried on the land.

A public footpath crosses the sewage farm at Abingdon. There has been no complaint from bad odor.

Babut du Maris says, "It has been claimed that prolonged irrigation will produce disease by the presence of bacteria in the sewage. Experience is to the contrary. The farms at Edinburgh have received sewage for more than two centuries, that at Buntzlau for two and a half centuries, and for more than ten centuries this has been in practice in China. Vegetation has never ceased to be vigorous and healthy, and the inhabitants have never been known to suffer in consequence of irrigation."

I am informed by a gentleman who has resided seven or eight years in China that in all the large cities the detritus is carried into the suburbs by hand buckets and deposited on the land for the benefit of vegetation, and in many instances the same pails serve to bring back drinking water, with no ill effect except in a few northern cities, where the sewage is put on the leaves of vegetation; there the tape-worm is very common. Dr. Williams, in his work entitled "The Middle Kingdom," does not include typhus, typhoid, scarlet fever, or diphtheria in a list of the prevalent diseases of China.

[1] Hutchinson remarks of this drug and of its derivatives: "Not even the syphilitic virus itself is capable of producing a greater multiplicity of pathological changes in the integument. Now it is a hæmorrhage, now a thrombosis, now an erythema, now a bulla; the commonest of all forms is an acne; but in addition to it and to those I have named we may have, at the same time, pustules, button-like tubercles, and in aggravated cases enormous soft tuberous growths."

[1] Concluded from page 580.

It is difficult to make comparisons or draw conclusions when considering this question financially, for the paramount objects to be attained vary in different communities. One town may seek only to get rid of the sewage, another its most profitable employment on the land, another relief from the pollution of a water-course or preservation of its navigability; grotesque and unprofitable experiments and local conditions all contributing to make balance sheets of great diversity in showing either profit or loss. Many examples of each are available, and should of course be carefully studied.

The city of Paris, for many years harassed by constant complaint and litigation as a result of discharging sewage in the Seine, some years since established sewage farms on the plains of Gennevilliers, the history of which is told in a report to the municipal council by the sixth Commission appointed to treat with the state for the concession of such public lands at Achères as are necessary for the epuration of the sewage by irrigation and agriculture.

Before the execution of the measures conceived by M. Belgrand for the general healthfulness of Paris, the rain water and the washings of the streets flowed into the Seine, either directly, or by a great number of drains emptying on the quays of each bank the whole length of Paris. This mode of drainage resulted in the immediate and pronounced pollution of the river, which reached the maximum at the point where it leaves the city. The work of Belgrand had for its result the concentration of four fifths of the drain water in a large sewer opening into the river at Clichy while the remainder was discharged at St. Denis. At the same time the water for domestic supply was largely increased. In 1860 30,000,000 gallons per day were furnished for this purpose; in 1882 92,000,000 gallons were required each day, or 34,020,000,000 gallons per year. This, with the rain water which falls on the city, estimated at from 9,576,000,000 to 11,340,000,000 gallons, makes a total of 44,100,000,000 to 45,360,000,000 gallons, which, were it not for evaporation and other loss, should be carried by the sewers. This loss amounts to something like 18,900,000,000 gallons per year as indicated by gauges in the two sewers, which register 26,208,000,000 gallons, — about 42 per cent. disappearing by evaporation. At low water of the Seine it is equal to one part of drain water to twenty of river water, and at high water to one part in 350. As a result of currents and obstacles in the river, mixing did not take place; and the right bank — the most densely peopled — received on a very long margin the totality of the drain water, depositing all the way organic matter brought in suspension. Protestations from people living along the right bank of the river followed very closely the opening of the two great sewers; and the state government required the city of Paris to seriously consider methods of purifying the sewage before discharging it into the river. The savants, engineers, chemists, traders, and agriculturists discussed the subject in all its phases, and to the latter we are indebted for a practical solution of the problem.

Filtrage was naturally the first system to be tried. It was soon found that, besides the actual difficulties of filtration on so large a scale, this mode of treatment had the capital vice of leaving in the water soluble organic matter capable of fermentation, and later, chemical agents were resorted to with the object of precipitating the soluble matter, but only incomplete results were obtained, which were slow, costly, and inapplicable on so large a scale.

We now come to the experiment which after fifteen years of study and persevering effort has given a result most complete and satisfactory. Epuration and utilization by agriculture, and filtration by spreading the sewage on permeable land have accomplished this end. It is based on simple principles, of which the demonstration is now made. All argilo-silicious and permeable soils, sufficiently thick and well drained, have the property of retaining in their superior layers all the organic matter in suspension and solution contained in drain water spread on the surface of the land. Such soil can receive without being made damp or marshy one inch of water per day, or twenty-six feet per year. It transforms the retained organic matter, rendering it capable of assimilation by plants. A very ingenious experiment just made shows this valuable property in the vegetable mould. A hollow column two metres in height was filled with earth in a manner to reproduce exactly the soil as found at Gennevilliers. Through this was passed sewage in a relative quantity to that employed in irrigation and at equal intervals with its use on the land. Epuration took place as completely as in the natural earth. Chloroform was then passed through the column, which at once arrested epuration, and the sewage traversed the column without being purified. Paralyzation of the infusoria stopped oxidation of the organic matter. This experiment has been demonstrated by M. Schloessing, and is described in the report to the Council of Hygiene. If the surface irrigated is under cultivation the fertilizing matter is immediately utilized; if not, it accumulates without loss and transforms the poorest soil into land of extreme fertility.

A very large proportion of the water used in irrigation is evaporated either directly or by the plants in vegetation. The residuary water coming from the subsoil drains is of a remarkable purity, and does not suggest either by aspect or composition the sewage from which it proceeds. Irrigation is the most economical and efficacious means of conveying directly to the plants the fertilizing matter of sewage.

Trusting in these principles, and fortified by the works of Messrs. De Freycinet, Schloessing, Marié-Davy, and Frankland, the engineers of the municipal service have, since 1867, pursued studies and made experiments for which, notably since 1872, the council has furnished a large amount of money. These efforts have had as a result the great and actual demonstration at Gennevilliers, which evidence impresses favorably all unprejudiced persons who take the trouble to visit the lands.

After some experimental cultivation at Clichy in 1867 and 1868 the irrigation of the plains of Gennevilliers was begun in 1869 by Messrs. Mille and Durand-Claye. In 1870 and 1872 the territory comprised but a few hectares. It has increased each year, until now over 500 hectares are thus employed (about 1200 acres, which receive nearly one fourth the sewage of the city). In the beginning the water distributed was limited to a few thousand cubic metres. In 1872 444,000,000 gallons were used. In 1881 4,685,000,000 gallons were discharged on the land. In May of this year (1881) 684,300,000 gallons — 22,050,000 gallons per day, or 44,100 gallons per hectare per day — these plains absorbed. In 1882, at the time of the report, the distribution reached 34,020,000

gallons per day, or 79,300 gallons per hectare, which represents a sheet of water spread over the surface equal to a little over one inch per day.

The progress, the slowness of which astonishes us now, has not been obtained without difficulty. At the origin, the engineers, relying too much on the very great permeability of the land, had not thought it necessary to establish subsoil drainage. The natural drainage, in consequence of an abundant irrigation, was found insufficient. The level of the subsoil water rose; a few cellars were flooded at Gennevilliers, and gravel quarries were inundated. This was sufficient excuse for a claim for excessive damages against so rich a victim as the city of Paris. To increase the indemnity and to compel a compromise, all possible arguments were employed. Doctor was opposed to doctor, and hygienist to statistician, when it was only a question of a few thousand francs damage to the claimants. These demands were opposed by the engineers, who in turn were very decidedly sustained and supplied with money by the municipal council. The necessary work to insure the drainage of the plains and to remove all pretext for damages was done, and to-day the complaint is rather of the lowering of the subsoil water. Nevertheless irrigation at Gennevilliers created a prosperity until then unknown, and a time arrived when the community, frightened by the possible result of its demands and outcries, — which threatened to be the suppression of irrigation, — asked for a contract, the principal article of which was that the city should engage to continue irrigation on the plains of Gennevilliers for twelve years.

The efficacy of this system of epuration is manifest, and presents a brilliant proof. The effluent drain water has fewer micro-organisms than the water of the Seine when it enters Paris. It has the purity of spring water coming from the earth. To demonstrate the utility of the system as applied to agriculture has been slow and difficult, and not less laborious than to test the efficacy of the epuration.

The slowness of experiments in agriculture may be understood when we remember that to reach an end we must go through all the phases of vegetation, from the sowing of the seed to the harvest. Under our climate it is a campaign of a year. If we neglect a detail, if we make a mistake at the time of sowing or planting, at the time of plowing or watering, the harvest may be a failure, and we must begin again. The difficulty was increased by local circumstances. Amongst the cultivators of land in the suburbs of Paris, no one knew the practical working of a sewage farm. One of the persistent workers who has been rewarded by success said recently that it required more than four years to acquire the necessary knowledge. To-day the cultivators are in complete possession of their art, and in the recent horticultural exhibition every one admired the remarkable products, which received honorable distinctions.

In agriculture, successes which would be shown by beautiful samples obtained in the fields of experiment would be objects of curiosity. It is necessary to secure economical results, and these go far beyond the utmost expectations. For the landlord of the soil the rent value of the hectare has increased fivefold, from ninety to 450 francs. For the farmer or cultivator the prosperity has not been less. The net value of vegetable products rose from little or nothing to 4000 francs per hectare.

In a sanitary point of view the results have not been less satisfactory, and here again it is necessary to observe the facts on the ground. One sees a numerous population, robust and healthy in proportion to its prosperity. Its vigor assures a healthy nutrition equivalent to its works, which is the best hygiene.

As to the effects of irrigation, the same occurs at Gennevilliers which always takes place where irrigation is practiced: from the moment it is made frequent, without stagnation, and at regular intervals, a condition which is far from favorable for the development of paludal influences. The determining causes are eliminated; a constant activity is maintained in the vegetable life, which absorbs in its circulation all its own residues and all the organic elements placed within reach. Highly to the honor of the city of Paris be it said that, by the perseverance of its representatives, by the science and devotion of its engineers, the problem of epuration of the residues of cities and of their utilization by agriculture is absolutely and definitely solved. We have no longer the experiment of Gennevilliers; we have a system permanent and regular for the future.

The population of Gennevilliers has increased by farmers coming to occupy the lands thirty-four per cent. in ten years.

Among the city documents of Paris lately presented to the city of Boston, and placed in the Public Library, may be seen photographs of the departments of this branch of the municipal service, as well as of the products of the land. The commission, in recommending the acceptance by the city of the terms which the state proposes for the extension of the work so as to include the sewage of the entire city, recommends a municipal ordinance which shall require all the water-closets in the city to be connected with the drains, and an absolute abandonment of cess-pools, which now are so common in Paris. Up to the present time the city has declined to accede to the terms of the state, as they are deemed too exacting, and require a very large amount of money for the purchase of the land. The success of epuration by this method is not questioned. The work of Babut du Maris, lately published, says "the city has just obtained 2500 acres for the extension of the sewage farm."

The highly satisfactory operation of this system at Dantzic, where the rigorous climate of winter is as great an obstacle to overcome as here in Massachusetts, is sufficient proof that frost is not an objection to its employment on our soil. The land freezes four feet deep at Dantzic. The Vistula is frozen over from the middle of November to March, yet the temperature of the sewage at the mouth of the sewer never goes below 37° F. Irrigation is continued throughout the year with quite as much success in epuration in winter as in summer, although vegetation flourishes but four out of the twelve months.

Sewage in freezing, says Babut du Maris, eliminates its dissolved fertilizing material as thoroughly as salt water eliminates salt by the same process.

There must be abundance of land in the valley of the Blackstone, the Merrimac, and the Connecticut suitable for farms of this character. There is land bordering on Lake Cochituate well adapted to farming, for the protection of the lake from the sewage of Pegan Brook. In Arlington, Belmont, and Medford are vegetable farms favorably located, and soil well suited to this system; and before this community embarks in a scheme to build a metropolitan sewer from Natick to

tide-water, which when finished will be of doubtful utility, judging from the experience of London, this system should be tested, with the object of requiring each and every community to take care of its own sewage.

We have in the soil a chemical laboratory, a perfect filter, oxidation, vegetation, the influences of animal life and the infusoria combining to protect the subsoil water, and so far as experience goes or chemical analyses can demonstrate, these processes of nature are amply sufficient.

We do not hesitate to cover with fertilizing material fields in which are located springs and wells. We are only solicitous lest the surface water should convey the material to them, and we raise an embankment above the level of the surrounding land, and otherwise leave to nature the protection of our drinking water with full confidence in "*vis conservatrix naturæ*," and if her processes are not complete and perfect the whole world is gradually becoming saturated with filth.

PROGRESS IN DENTISTRY.[1]

BY WILLIAM HERBERT ROLLINS.

D.

1. — PYORRHŒA ALVEOLARIS.

Many theories have been advanced to explain the origin of this disease. A. Witzel, in a paper read before the German Dental Association,[2] states that the disease is not an ulceration of the gum or a primary inflammation of the dental periosteum, but is a caries of the dental alveoli, caused by a septic irritation of the medulla of the bone. He advises extraction of all teeth where the sockets have been destroyed for one half their length. The other teeth are to be thoroughly cleaned, and a strong (?) solution of carbolic acid (one to one hundred) is to be injected into the pockets by means of a syringe.

2. — CAUSES OF CARIES.

The most important investigations recently made to determine the nature of decay in the teeth are those of W. D. Miller. He finds that the dentine when attacked by decay shows, even in the deepest layers, a loss of lime salts. This loss is a real solution by acids, and cannot be accounted for by the action of any agent which affects only the organic matter of the teeth. This view of the matter is contrary to the statements of the editor of the *New England Journal of Dentistry*, who found that the lime salts were but slightly diminished, and that no lime in combination with organic acids could be found in decayed dentine. He therefore reasoned that acids played no part in decay. Miller, in support of his view, has made many thousand experiments and cultures, a brief outline of which may be of interest. He put some starch into a small tube, which was tied to a molar tooth, and kept in the mouth over night. In the morning the contents of the tube were acid. Both the starch and the tube were sterilized before placing in the mouth. The same result occurred in a mixture of fresh saliva and starch out of the mouth, but if the mixture of starch and saliva were heated to 100° C. it did not become acid. The ferment, therefore, existed in the saliva. To determine whether it was organized or unorganized the saliva was shaken in a test tube with sulphuric ether, starch was then added, and the mixture put in an incubator. After a few hours sugar could be found, but no acid. The acidity found in the first experiments must, therefore, have been due to an organized ferment (fungi). A mixture of saliva and grape sugar was exposed to a temperature of 67° C. for twenty minutes. In a few hours it became acid. This confirmed the previous experiment, as the ptyaline must have been killed by the heat, so the acid could only have come from the germs present in the mixture. A perfectly sterilized mixture of saliva and sugar was exposed to the action of a piece of decayed dentine the size of a pin-head. In a few hours it became acid. A drop of this mixture infected other sterilized solutions. This could be carried on indefinitely. It was, therefore, evident that the ferment had the power of reproduction, which was an additional proof that it was an organized body.

To determine the nature of the acid fresh saliva was mixed with starch, and allowed to ferment. The mixture was then filtered and heated to 100° C. The filtrate was evaporated to concentrate it. A few drops of it added to methyl violet did not change the color. The remainder of the filtrate was shaken with sulphurous ether. When the ether became clear it was distilled. A portion of the residue was found by a polaris trobometer to be optically inactive. The remainder was mixed with oxide of zinc, boiled and filtered. Crystals of lactate of zinc were found in the filtrate.

To see if the fungi were capable of producing caries out of the mouth pieces of dentine were placed in a mixture of sterilized saliva and starch, which was then infected with a pure culture of the fungus found in the deepest layers of decayed dentine. When these pieces were afterwards examined under the microscope it was found impossible to distinguish them from dentine affected by natural caries. Miller thinks he has shown that caries is due to a fungus which generates lactic acid, the acid acting on the lime salts. When these have been dissolved other germs finish the work by destroying the organic basis of the dentine. Among these latter germs bacterium termo is always present.

Underwood and Milles, who have been investigating the same subject, also consider that germs play an important part in caries. They do not think Miller's investigations reliable, because they have always found that no invaded tubule in carious dentine contains more than one form of fungi. If cocci are present in one tube they are never mixed with threads or bacilli, though either of these forms may be present in adjacent tubes. They state that Miller in figuring several forms in the same tube has proved his ignorance of the nature and methods of growth of these organisms. Their experiments do not seem, however, to have been made with the same amount of care that Miller has shown, nor have they reached any very definite conclusion.

3. — COURSE OF CARIES.

According to Miller starch and saliva at the temperature of the body become acid in a few hours. Therefore in every mouth acid is generated, and capillary attraction will draw this into the minute pits and fissures of the enamel. The extent to which the acid will act depends directly on its strength, and inversely upon the density of the tooth. The superficial layers of dentine completely lose their lime salts. The same

[1] Continued from page 584.
[2] New England Journal of Dentistry, May, 1883.

is true of dentine in bread and saliva out of the mouth. The destruction of the organic basis of the dentine soon follows the solution of its lime salts, and is caused by germs. The fungi of the mouth do not directly decalcify dentine; they do this through the lactic acid, which is generated from sugar and starch.

4. — DISEASES OF THE EYE PRODUCED BY CARIOUS TEETH.

Dr. Galezowski mentions [1] several diseases of the eye caused by dental irritation. They are reflex asthenopia, reflex kerato iritis and irido choroiditis, reflex mydriasis, and spasmodic contraction of the lids and of the oculo motor muscles.

5. — SYPHILITIC INOCULATION FROM A DENTAL INSTRUMENT.

Dr. J. T. Tripp reports [2] a case. Though seldom mentioned, such cases are probably not rare. They show the great importance of keeping all dental instruments perfectly clean, for not only syphilis but other diseases may be contracted in this way. If every dentist would make it a rule never to use an instrument which was not perfectly bright the danger would be much diminished, as the care required to keep the instruments in this condition would be pretty sure to make them incapable of inoculating.

6. — REFLEX IRRITATION FROM DENTAL CARIES.[3]

For four years the patient, a young girl, was attacked once a week with violent contractions of the muscles on the left side of her face, the head at the same time being drawn down to the shoulder. These contractions had produced a great prominence of the muscles of the affected side. On extraction of a decayed molar the contractions ceased.

7. — CONGESTION OF TONGUE CAUSED BY CELLULOID.

Dr. Brownlee reports [4] a case. The palate, lips, and cheeks in contact with the celluloid were highly congested. The tongue was much swollen, deeply grooved, and bright scarlet. The pain was constant and increasing. No treatment was given except to make a new set of teeth on rubber instead of celluloid. The parts returned to their normal condition in a few weeks.

E.

1. — LIME IN THE TREATMENT OF SENSITIVE DENTINE.

P. Calvo recommends the following treatment: First dry the cavity, then put in fresh, dry lime and seal the opening. In this way the action of the lime extends over some time so that it does not give rise to pain as it will do if water is allowed to come in contact with it immediately. He states that the dentine loses its sensibility without any risk of injury to the pulp.

2. — SODIUM CARBONATE IN TREATING ROOT CANALS.

Dr. Kirk packs the root canal and pulp chamber with the salt in powder, and then fills the remainder of the cavity with a temporary filling. After a few days the latter is removed, and the soda washed out. The canal will then be found perfectly free from odor.

[2] British Journal of Dental Science, page 77, 1883.
[3] British Journal of Dental Science, January 1, 1884.
[4] British Dental Journal, January, 1884.

3. — MENTHOL IN THE TREATMENT OF INFLAMED PULPS.

A saturated solution of the crystals in alcohol has been found of value as an application for the relief of pain caused by exposure of the pulp. Its use in pyorrhœa alveolaris has also been recommended in the form of an injection into the pockets formed between the root and its periosteum.

4. — NITROUS OXIDE AND OXYGEN.

The suggestion of Paul Bert to use a mixture of nitrous oxide and oxygen to prolong the effect of a primary inhalation of nitrous oxide has been found of value.

5. — ACTION OF ARSENIC ON THE DENTAL PULPS.

Bödecker has studied the effect of this much-used pulp destroyer, and has published his results.[5] Witzel had stated that arsenic was an admirable agent in the treatment of suppurating pulps, the upper parts of which were excised after the application. He said the body of the pulp remained healthy, and that the treatment was a valuable one. Bödecker tried it, but finding it unsuccessful made a series of experiments, of which the following is an abstract: Holes were drilled into the dentine, taking care not to reach the pulp chamber. A layer of sound dentine was, therefore, present between the arsenic and the pulp. The teeth were extracted in from three to six days after the application. They were then immediately opened and put into the proper reagents. An examination of the nerve fibres showed that the myelin was separated into irregular masses. When the arsenic had acted for six days he found a granular substance in the fibres, which was colored by rose aniline. All vestiges of the myelin had disappeared, globules stained black by hyperosmic acid taking its place. Viewed under the microscope the dentine tubes in sections, stained with hyperosmic acid, showed, in the vicinity of the hole in which arsenic had been placed, much enlargement. They were filled with irregularly-shaped, black bodies, which were supposed to be altered fibrils, because in following up a tube containing them he found the dentine fibres less changed as they receded from the centre of inflammation. The increase in the diameter of the tubes had taken place by an invasion of the basis tissue, which had also lost part of its lime salts.

Hospital Practice and Clinical Memoranda.

BOSTON CITY HOSPITAL.

MEDICAL SERVICE. UNUSUAL CASES OF SCURVY.

REPORTED BY R. T. EDES, M. D.,
Visiting Physician.

The British ship Earl Granville sailed from Iloilo, around the Cape of Good Hope, on August 4th, with a crew of thirteen men, beside five who messed in the cabin. There occurred on board several cases of a peculiar character, three of which were sent to the Boston City Hospital, and seem to be of sufficient interest to be reported.

It will be noticed that the dates given by the hospital books, which represent the statements of the patients themselves, do not agree with those taken from

[5] Dental Cosmos, October, 1883.

the ship's log. The latter undoubtedly mean, not the beginning of the sickness, but the days on which the patients became too sick to work.

The food, as required by the scale of provisions in the articles of agreement, is said to have been good and abundant. The water was good, if some rain-water caught (as far as could be ascertained some time in November) be excepted. This water was used for about a week after being caught, but its use was discontinued when from its appearance and an oily or tarry surface it was suspected that it might not be wholesome. The officers drank this water, but for those in the cabin it was filtered. The men represent this water as having dripped from the masts and rigging and recently-painted deck-houses, and as having been very bad. This is somewhat doubtful.

From all that has been learned it is believed that the men were supplied with a certain amount of lime-juice and antiscorbutic food, but that the first was not given as soon as it ought to have been, and the latter not in sufficient quantity to prevent or cure sickness in the case of men who, in consequence of other complications, or from a predisposition to scurvy when they commenced the voyage, were injuriously affected by salt provisions.

The following are entries taken from the master's log: —

William B., October 25th, stricture. Returned to duty November 24th.

William C., December 6th, feet and legs swelling, appearing to have dropsy. Died on January 31st.

Mauritz C., January 18th, feet and legs swelling.

John R., January 25th, scurvy.

Olinto C., January 28th, pains in legs, and feet swelling.

James B., January 29th, legs swelling.

William B., January 29th, stoppage of water, and severe pains in legs and body.

The cases after entering the hospital were as follows: —

William B., aged thirty-seven, entered February 9th. Three months ago, after a slight cold, began to swell all over body. Severe pain in left chest. He had dyspnœa for the last five weeks. No headache or vertigo, but occasionally vomiting and twitching of his face. He had had severe pain on passing water, and was obliged to have it drawn by catheter. On entry, his abdomen was tense and hard, and he said that he had passed no water for two days. The penis was swollen, and the catheter obstructed about the membranous portion of the urethra. These local troubles, according to his own statement and the ship's log, antedate the present illness. He was markedly dropsical on entrance, but the swelling rapidly disappeared in a few days. He was said to have much dyspnœa on entrance, but this improved so rapidly that there was little to be seen of it when the visit was made the next morning. There were no ecchymoses, nor sponginess of the gums, although he alluded to some trivial hæmorrhage. The urine of the 10th was of specific gravity 1017, with a slight trace of albumen, pus, and some bladder epithelium. Nothing abnormal was detected in the thorax by auscultation. He had a hot-air bath. On the 20th the urine was of specific gravity 1020, with a slight trace of albumen, pus, blood, uric acid, large epithelium, and hyaline and granular casts. For a few days he had a mottled eruption, composed of rounded spots about one eighth of an inch in diameter, partially confluent, and preceded by pustules, said to have come on six weeks before. He was discharged on the 23d, well.

Olinto C., aged thirty-five, entered February 9th. Does not drink. Has had gonorrhœa and chancroids. Three months ago noticed general weakness, with some stiffness in knees and ankles. Seven weeks ago legs and ankles began to swell, and there was dyspnœa on exertion, but he did not give up work until eleven days ago. He noticed some palpitation a week ago, and cough four days ago. His throat had been sore for four months. On entering, he complains of dull pain in his chest, and also on the right side of the body. There is some œdema of feet and ankles and legs. The gums were slightly anæmic, but there was no marked sponginess. There were no hæmorrhagic spots or indications thereof. The cardiac area was increased, the apex beat felt just to the outside of the nipple. There was a slight roughening of the first sound at the apex, and a marked thrill. The patient gradually improved, but on March 1st it was noticed that he had no patella reflex, and he complained of stiffness and pain in the legs, and had some difficulty in using them. The muscles were well developed and hard, perhaps somewhat abnormally so, and reacted only feebly to a strong faradic current. The muscles above the thigh reacted well. On March 22d he was discharged, much relieved.

Moritz C., aged twenty-eight, born in Finland. Entered February 14th. Was always well until six weeks ago, when crossing the line; then felt chilly, and could not keep warm. His legs began to swell, and the swelling extended to his body and face. There was slight headache, but no vertigo. The appetite was fair and the bowels regular. There had been dyspnœa for four weeks, gradually increasing, and for several nights past it had been so severe as to prevent his sleeping. Some cough for three or four days. Temperature 101° F. Pulse 120. When first visited he was seen to be a short, powerfully-built man, of fair complexion, in a state of urgent dyspnœa, the countenance being somewhat dusky, and wet with perspiration, which was said to have come on rather recently, and, it was hoped, was a sign of approaching relief. The anasarca was general, but not extreme at any one point. There were no distinct hæmorrhages, but some purplish spots on his wrists and hands, and a few on the body. The teeth and gums showed nothing abnormal, except a barely perceptible swelling, which had not bled. Both chests were full of moist râles. There was nothing abnormal about the cardiac sounds. The urine was normal in color, of specific gravity 1027, containing one fourth of one per cent. of albumen, with a sediment of amorphous urates, and an occasional blood, pus, or epithelial cell. The dyspnœa became more and more urgent, the râles more abundant, the expectoration frothy and bloody, the cyanosis increased, and he died in the morning, two days after admission.

The treatment consisted in diffusible stimulants, ammonia, and alcohol. The orthopnœa would have made a hot-air bath difficult to administer, and the presence of abundant perspiration made it appear improbable that any further action on the skin would be of value.

The anæmic appearance of the patient, combined with the fact of the rapid relief and recovery of his comrade (Burns), whose condition had been similar, though less urgent, deterred me from venesection, which, I think, as the autopsy showed, would not have

been efficacious. Nevertheless I think should such a case come again under my care I should bleed him.

The autopsy, made by Dr. Gannett, showed general anasarca, hypertrophy and dilatation of the heart, with relative insufficiency of the tricuspid valve. The heart muscle contained much finely granular, albuminous material, and considerable fat in the form of small drops. There was chronic adhesive pleurisy, with hydrothorax and œdema of the lungs, acute bronchitis, and acute bronchial pneumonia. The spleen was that of chronic passive congestion. The kidneys showed cloudy swelling, with interstitial nephritis. The epithelium of the convoluted tubes contained much finely granular albuminous matter, and a few small fat drops. The interstitial tissue was increased in thickness, showing in places a hyaline appearance, and in others a slight degree of round-cell infiltration.

Incisions made through some of the purple spots mentioned above disclosed no ecchymoses, and nothing like extravasations, new or old, were found, either in the internal organs, the soft tissues of the legs, or under the periosteum of the tibia.

The two men who did not go to the hospital are supposed to have shipped again, as they have not been heard of at the consul's office. William B. is also supposed to have shipped, and Olinto C., who was discharged relieved, was given a passage home.

It seems quite evident that there was little doubt in the minds of those who first saw these cases that they were scurvy, a disease usually susceptible, from its striking symptoms and the peculiar circumstances under which it arises, of easy diagnosis. The point, however, which will most strike the attention in accepting this diagnosis is the absence of the most usual and well-marked symptoms, namely, the hæmorrhages under the skin and from the mucous membranes, and also the spongy gums. In one case only which entered the hospital was there a barely perceptible swelling of the gums, and in only one or two the most trivial hæmorrhage. The men in the hospital gave no history, although questioned, of having had themselves sore mouths or hæmorrhages, or of having known of these conditions in their comrades who did not enter. The pain and swelling were, or had been, the chief symptoms in all that we saw, and in two that we did not see. Only one of the six men was called a case of scurvy on the log.

Army surgeons speak of cases in which the most characteristic symptoms are wanting while yet the cachexia exists, so that "general debility" on a report may mean scurvy. We can hardly, however, call our cases, which had been going on for many weeks, as Flint says such cases may be regarded as "incipient," though they may be "not fully developed."

No author whom I have consulted makes any statement of the conditions under which we may expect such departures from the ordinary type of scurvy, one set of symptoms being almost entirely absent while others are present in their full severity, sufficient to cause death in two cases out of six. We can hardly, in presence of a group of six cases, involving at least three nationalities (English, Italian, Finnish), speak of "individual" peculiarities, and these cases, therefore, lend an additional support to the doctrine that in the ætiology of ordinary scurvy there are involved several factors, of which the deprivation of fresh vegetables is only one, though perhaps the most important.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.

SPECIAL MEETING.

ALBERT N. BLODGETT, M. D., SECRETARY.

APRIL 30, 1884. Meeting called to order at eight o'clock by DR. R. T. EDES, chairman.

The first paper was by DR. HENRY J. BARNES, upon

SEWAGE SYSTEMS AND THE EPURATION OF SEWAGE BY IRRIGATION AND AGRICULTURE.

The paper was received with applause by an audience composed of physicians and a large number of sanitarians and sanitary engineers, as well as a number of delegates from the Sanitary Boards of towns about Boston, the superintendent and physician of the Woman's Prison at Sherborn, representatives from Natick and various other places.

DR. GEORGE B. SHATTUCK, in opening the discussion of the subject, said that he only consented to do so in the hope that others better acquainted with it, and who had personally inspected the sewage farms at Gennevilliers, at Berlin, Dantzic, and in England, might be induced to give their views. As the Society was fortunate enough to enjoy the presence of past and present members of the State and City Boards of Health, as well as of several able and distinguished engineers, he felt sure justice would be done the subject, than which none more important awaits regulation in the older Eastern States, and he would confine himself to a brief statement of the general methods of the disposal of sewage as at present understood and practiced. These may be included under three heads: (1) immediate discharge into some neighboring body of water, stream, lake, or ocean; (2) chemical precipitation of solid constituents; (3) discharge upon land to be disposed of by downward filtration through the soil or by broad irrigation for purposes of agriculture and fertilization.

The method of chemical precipitation might, as Dr. Barnes's interesting paper plainly showed, be left out of consideration as unsolved. Of the other two methods the first was comparatively simple, satisfactory, and inexpensive, where there was in the immediate neighborhood a large body of deep water moved by tides or currents sufficiently active to carry off or oxygenize the sewage without its becoming a nuisance to other places in the process. Boston, the speaker thought, was so situated.

In discussing the disposal of sewage by the aid of the soil Dr. Shattuck said the systems of downward filtration for epuration, or of broad irrigation for agricultural purposes, ought to be carefully distinguished from each other, it being possible, as a rule, to use a larger and less variable amount of fluid in the former than in the latter method. The successful application of either of these systems must be governed by many variable factors, so that no general laws had been or probably would be arrived at. Each place must work out its own problem and its own sewage salvation. In discussing sewage-farming one must bear in mind the character of the soil, whether sand, clay, or loam; the character of the climate, whether moist or dry, hot or

cold, or variable; the kind of crop for which there is a market, whether coarse grass or garden vegetables; and last, but not least, the composition of the sewage itself, the proportion of solid constituents to liquid as determined by rainfall or by *per capita* amount of water used or quantity of solids admitted to the sewers.

It should not be forgotten that the present sewage irrigation at Gennevilliers was voluntary with the farmers, who used it or not as they chose, and the calculation of 2000 hectares (about 5000 acres) with which to handle the whole of the 110,000,000 cubic metres of annual sewage of the city of Paris, the speaker thought, must be based rather upon the system of downward filtration than upon that of broad irrigation for agriculture.[1] Dr. Shattuck was not aware of any application of sewage-farming upon a large scale which had proved actually profitable. It would generally, he thought, prove a question of comparative cost.

MR. E. W. BOWDITCH, sanitary engineer, stated that the assertion which was contained in the paper that the water supply of Chicago is contaminated with sewage from the city is not probably correct. A year ago there was no positive proof of the truth of this statement, although the time will come when this will be true unless the crib for the supply is carried farther out into the lake. In regard to the frequency of the cleansing of the cess-pools so frequently attached to dwellings in cities, an incident occurred a few days ago which illustrated the average degree of sanitary knowledge possessed by the average citizen. A gentleman in speaking of cess-pools stated that one great objection to their use consisted in the necessity for their periodical emptying and cleansing. During further conversation the fact was disclosed that the cess-pool on the premises occupied by the gentleman had not been emptied in eight years.

The accessible reports on the disposal of sewage by the aid of irrigation and agriculture do not agree, thus making it very difficult to arrive at any definite opinion upon the merits of any special plan. Probably, too, each particular locality and each individual system presents different conditions, and has its own particular drawbacks.

At Pullman, Ill., which has been considered the model of disposal of sewage by and of agriculture, it is said that this plan has been abandoned, and that the sewage is now poured into Lake Michigan.

As far as Massachusetts is concerned there can be but little question that the rigorous climate of our winters would seriously interfere with the filtration of sewage in the colder months, and there is lack of enthusiasm among the farmers to test the efficacy of the plan.

The sewage of the Mystic Valley corresponds exactly to what it is supposed to be. It is possible and quite probable that a series of filters would be useful in clarifying the foul water of this sewer, though it would not purify it. Some time ago a barrel of Mystic sewage was sent to New York to be used as a test for a process for purifying foul water. Upon return of the purified product it was found to be free from any offensive quality. At the same time a sample of water which receives the drainage of sixty tanneries was also forwarded, and this, although originally very much polluted, was returned free from any offense, and has remained sweet and clean for a period of many months.

The general question of sewerage is daily assuming a more prominent position among the economical topics of our towns and cities. Of 346 towns in the Commonwealth eighty-four have already introduced works for public water service. Of these eighty-four towns twenty-six have also sewerage systems, while the other fifty-eight have water brought to them, but no means of its removal. These towns will be obliged to adopt some means of purifying or disposing of sewage in order to obviate nuisance which must otherwise inevitably arise. It is not easy to see how towns more than ten miles from Boston could possibly unite on or derive benefit from a metropolitan sewer. The cost would be too high, and the towns could not possibly afford it. From experiments which have been made with the object of forming an opinion on this subject, and which have been quite extensive, it would seem that the most practical solution of the sewage problem might be found in some process of purification.

DR. H. P. WALCOTT, of the Massachusetts State Board of Health, in response to a call from the chair, spoke as follows: The statements of previous speakers render any general discussion of the subject of irrigation unnecessary, and I shall, therefore, confine myself to the sewage farms of Berlin, having had very favorable opportunities for studying them. To me they represent the best experiment thus far made in sewage disposal by way of irrigation, far more complete than anything of the sort in England or France.

Two farms, Falkenberg on the northeast, and Osdorf at the south, are the localities at present made use of. The acreage has been steadily increasing, and now (1884) appears to be between nine and ten thousand acres, of course not all prepared, perhaps not tweny per cent.; Falkenberg so incomplete as to be in an unsatisfactory condition; Osdorf, in the finished parts, eminently satisfactory; no smells except localized ones about outlets of sewer; soil under-drained; effluent from subsoil drains, clear, free from smell or taste, as good as the average drinking water of Berlin. In the earlier days of the farm the principal crops, rye grass and cabbage, were readily sold at remunerative prices; the markets are, however, now overstocked in these articles, even though large quantities have been sold in markets comparatively distant from Berlin.

The sewage question in Berlin has, however, never depended upon financial considerations; irrigation (from the height of water level in the soil and very slight fall in many miles below Berlin of the river Spree) was a necessity, something to be had at any cost. Enormous as this cost has been the money is shown to have been well spent by the improved sanitary condition of the city, therefore any money return is so much gained. There is one arrangement at the Berlin fields open to serious criticism, the so-called winter basins, into which sewage is run during seasons of the year when crops are not in growth. These are many acres in extent, act simply as filters, receive sewage in very large quantities, which occasions an offensive deposit, to be plowed into the soil in the spring, the ground then planted with grain, and receives no more sewage except in case of drought. These basins are for a time quite offensive, and would not, I think, be tolerated in this country. Gennevilliers lacks one of the great elements of success at Berlin, the strict control by competent authority. At Gennevilliers the farmer

[1] At least it allowed about fifteen times as much sewage to the acre as was thought desirable for agricultural purposes by the commission appointed to consider the best disposition of the sewage of the city of Worcester.

takes the sewage or not as seems best to him. Upon one visit to Gennevilliers no sewage at all was being disposed of by irrigation; all was going to the river; this was naturally during damp, overcast weather.

No experiments of any value have been made in this country. Colonel Waring's system at Sherborn was very expensive in first outlay; does not furnish a satisfactory effluent. Broad irrigation at Insane Hospital at Worcester is a complete success, but under conditions which it would not be possible to imitate in many towns. It is to be hoped that the preparations for a system of irrigation for sewage of prison at Concord may be carried out, and give an opportunity for careful determination of questions as to evaporation, etc., which have never been studied in this country so far as irrigation fields are concerned.

Dr. C. F. Folsom said that there is no longer any doubt of the facts that sewage can be purified by irrigation, that the crops raised are suitable for food, and that sewage farms can be managed without creating a nuisance. This is all very expensive, however, and in no case has a sewage farm been carried on for any length of time, except on the scale of a few acres, in such a way as to satisfy the sanitary requirements of the case without the incurring of very considerable pecuniary loss. In Paris, Dantzic, and Berlin the loss is very considerable, but these cities are so situated that they must have sewage irrigation if they have sewerage, and the outlay on the sewers is reckoned with the deficit from the sewage farms as the cost of cleaning the cities and improving the public health. The great rise in the value of the land where sewage is used in irrigation near Paris is due to the fact that it is near an immense and rapidly growing city, and applies to land where sewage is not used as well as to the irrigated land. The soil, too, is of such a character that the farmers use wind-mills and ordinary irrigation for garden crops, and in some cases prefer it as being less offensive than the sewage.

There is no land in Eastern Massachusetts quite suited for sewage irrigation on a large scale, but near Worcester and Natick there is land which can be made available for that purpose just as soon as the authorities decide that the nuisance of the present methods of sewage disposal is great enough to justify the trouble and expense. If the sewage of Boston were used in irrigation there would be an annual loss to the city from that source alone of a sum somewhere between twenty thousand and fifty thousand dollars. The pecuniary value of the sewage of Boston can be estimated roughly by remembering that its strength is represented by the daily excrement of one person in three barrels of water, forming a fertilizer which no one would think worth much for daily use in his garden.

Alexis H. French, Esq., engineer for the town of Brookline, said: "In the present state of chemical and agricultural science an engineer would not be justified in departing very far from the practice that has heretofore been followed in the disposal of the sewage of the favorably situated cities and towns, in the simplest way possible, provided that this method did not menace the public health. Pending the discussion and experiments on the subject which, it is to be hoped, will be continued until some satisfactory solution will be obtained, the engineer has to face the question in the light of the existing information, and do the best for his clients that the circumstances will allow.

"In relation to the present systems of sewers it may be said in their favor that while it is more than probable that eventually some method of sewage disposal will be discovered which shall be unobjectionable in a sanitary point of view, if not in an economical one, these same systems will continue to collect the sewage, and will not, therefore, prove to be the vast financial loss which might seem to be the case from such a change in plan.

"One of the greatest obstacles to sewage irrigation in New England is the peculiar topography, this method of disposal, as I understand it, requiring comparatively level land, which, to take the drainage of our larger cities, must be several square miles in extent. It would, perhaps, be applicable to the smaller cities and towns, where the 'separate system of sewerage,' as it is called, is in use, and to those western cities which have near at hand large areas of prairie land favorably situated, both for receiving the sewage and for the subsoil drainage which this system necessitates."

Dr. John G. Blake said that when we succeed in obtaining a law which shall compel towns to take proper care of their sewer products, we shall have made a great advance in the solution of the question of irrigation and agriculture. There are certain weighty objections to be first overcome. It is well known that the population of Eastern Massachusetts is to a very large extent composed of the classes of artisans and mechanics, or manufacturers, and that agriculture as a commercial or economical pursuit is not cultivated to any considerable extent. This interposes a certain amount of indifference, and even opposition, to the introduction of irrigation and agriculture as hygienic measures.

There is reason to hope that within a short time the town of Natick, which is at present the gravest offender in the pollution of the Boston water supply, will be forced to purify its sewage products, and to render its waste water harmless before it is poured into the reservoir from which the citizens of Boston are now drinking.

In relation to the sewage problem in the Mystic Valley the condition of things there is not yet quite satisfactory. The water as it is now discharged is far from pure. The owner of a new filter, however, agrees to supply a series of filters which shall remove all suspended matter in the water, and we propose to dispose of the rest by irrigation. The city owns five acres of land which can be utilized for that purpose, and it is probable that the experiment will be tried, and, if found successful, it may be extended. Dr. Blake then moved that a special meeting be provided for the further consideration of the present subject, which was carried, and the Secretary was directed to arrange for such a meeting in the near future.

Adjourned at 10.15 P. M.

CONNECTICUT MEDICAL SOCIETY. NINETY-THIRD ANNUAL MEETING.

This Society, one of the oldest in the country, as only two or possibly three were organized before it, held a very successful and interesting Convention at New Haven May 28th and 29th.

NO CHANGE IN PLACES OF MEETING.

In accordance with an old custom arising from the two capitals which the State formerly had, the Society

meets alternately at Hartford and New Haven. A strong effort was made this year to break over this custom, now settled by a by-law of the Society, and meet every third year at Bridgeport. An effort was also made by a large number to have but one place hereafter, as the State has now but one capital. There would be many advantages in having but one place, which would be the headquarters of the Society; but the change was not made in either direction, the Society by a very decisive vote maintained the validity of the old custom.

The active growth of the Fairfield County Medical Society and their increased interest, as well as the known hospitality of Bridgeport, were urgently pleaded, but were not strong enough to induce the change. The chief cause, however, why this experiment was not at least tried was the precedent offered to other cities in the State to ask the same favor.

THE FELLOWS OF THE STATE SOCIETY.

The Fellows, so-called, made up of the officers of the Society and delegates elected from each of the eight county societies which make up the State Society, meet Wednesday for business. No others vote, although the members can attend, and if they have ever been elected to act as Fellows have all the privileges except voting. Most of the counties send four Fellows; one sends three. There has been a strong desire to increase the number for some time, and base the number sent upon the membership of the county societies, which varies greatly, three having a hundred or more each, the others not over fifty on an average; but the Charter fixes the number. Under the idea that by legislation in revising the Charter of the Medical Department of Yale the Charter of the Society had been undesignedly repealed, an amendment to the By-laws was offered basing representation upon membership, and making all ex-presidents permanent Fellows, but these were this year referred to a Committee on the Revision of the Charter.

PRESIDENT'S ADDRESS.

The Fellows met in convention, Wednesday, May 28th, at three o'clock. All parts of the State were well represented.

The President, DR. E. B. FRYE, after appointing a committee on credentials, welcomed the Fellows, as in duty bound, and called their attention to the subjects to which he thought special attention should be paid, the legal *status* of the Society, whether or no its Charter had been repealed by the Act of 1879, suggesting a new act to put the question beyond doubt. The proposed amendments to the By-laws met, for the most part, his approval. He spoke of the great progress of late in sanitary science, and of the duties of the profession as guides of the people. He unqualifiedly indorsed the Code; both his conscience and judgment caused him to indorse a code of ethics, but it should be intelligently construed; the claims of humanity are to be respected. He advocated a higher standard in medical education, and the maintenance of a high standard in the affairs of the Society. He alluded very appropriately to the death of distinguished honorary members of the Society, Drs. J. Marion Sims and Willard Parker, and to the members, including one recently president, Dr. Pliny Jewett, of New Haven.

COMMITTEES.

After the report of the Committee on Credentials, which included a list of those qualified to vote, the usual committees were appointed. On Unfinished Business, Drs. C. J. FOX, F. E. Beckwith, J. F. Calef. On County Resolves, M. Storrs, L. B. Almy, F. N. Braman. On Business, T. B. St. John, H. G. Howe, R. S. Goodwin. On Honorary Members, W. H. Mather, J. La Pierre, G. Clay. Auditing Committee, J. W. C. Foster, J. Olmstead. To Nominate Essayists, W. C. Wile, F. S. Crossfield.

RELATIONS WITH YALE COLLEGE.

PROF. C. A. LINDSLEY then announced that a committee had been appointed by the Corporation of Yale College to confer with the Society in regard to the severance of the relations between the College and the Society. It was voted that a committee of three be appointed for that purpose, and the President selected Drs. F. I. Dickinson, M. C. White, and Orlando Brown.

This committee afterwards reported that it was mutually desired by both parties to cancel and annul the relations heretofore existing between them, and that the officers of the Society be authorized to execute all papers requisite to obtain this end, it being understood that such separation shall be without prejudice to all vested interest, contract, or endowment of the College, and that any prerogative heretofore possessed by the Connecticut Medical Society shall revert to the same. The report was accepted without debate, and by this act the relationship between the Medical School and the Society virtually severed. Before the existence of the College, medical degrees and licenses to practice were granted by the State Society, and for many years no one could legally practice medicine in Connecticut unless he were a member of the State Society. The rise of Thompsonianism led to a bitter struggle, and to the repeal in this State of all restrictions upon the practice of medicine by law, and no law regulating medical practice, except one excluding itinerant quacks or medical tramps, has ever since been passed.

The Medical Society and the Medical Department of Yale College were chartered conjointly, and degrees conferred by a board of examiners appointed by the Society and its President, together with the professors of the Medical School. The Society also, by a committee, nominated the professors when any vacancy occurred. By this action, when completed, the entire control of the School will pass into the hands of the Corporation of Yale College, and no farther jurisdiction be exercised by the Medical Society. As the action cannot, in the opinion of the Corporation, be completed without farther legislation, the usual committees were this year appointed.

After the passage of the resolution Mr. Kingsbury, of Waterbury, a member of the committee on the part of the Corporation, was invited to speak about the measure just passed.

He said that the enlarged plan of medical instruction involved so much additional expense as to be burdensome to the Corporation. The increase in the facilities and means of instruction had not been followed by an increase in the number of students. The union between the Society and School had ceased to be useful, and its cessation was desired by both. An

endowment of the School was needed. He commended the School to the profession, and stated that its standard had never been better, nor its means for instruction. He commended the School to all students of medicine, and invited a close scrutiny of the institution and its methods by the assembled physicians, assured if they did make it they would advise all young men of their acquaintance who were students of medicine to attend.

The movement to separate was expected, and had been fully considered before the meeting of the Society. It is expected that there will be a closer union with the College; that in collateral branches better facilities will be afforded medical students. A determined effort to secure a proper endowment ought to succeed. There are enough in the State that could afford to do this, as President Porter said, in his after-dinner speech, in allusion to the small amounts that have been given to endow medical schools in comparison to the endowment of other departments.

THE LEGAL STATUS OF THE SOCIETY.

PROFESSOR CARMALT, as Secretary of the Committee on the Legal Status of the Society, reported that but one meeting had been held. An eminent legal firm, in Hartford, were employed to draw up a brief of the case, which was then submitted to Mr. Simeon E. Baldwin, of New Haven, for opinion. He stated that, in his judgment, the Act of 1879, revising the Charter of the Medical Department of Yale College, did not in any way affect the corporate existence of the Connecticut Medical Society. In this opinion the other lawyers referred to agreed. The report was accepted.

NOMINATING COMMITTEE.

A recess was then taken in order that the Fellows from each county should select a member to act on the Nominating Committee, which was reported as follows: M. Storrs, W. R. Bartlett, L. B. Almy, Seth Hill, C. J. Fox, L. J. Ketchum, F. D. Edgerton, C. F. Sumner.

UNFINISHED BUSINESS AND AMENDMENTS.

The first report called for was on Unfinished Business. The committee reported favorably on all except those amendments relating to an increase in the number of Fellows, which were unconstitutional. After some debate they were referred to a Committee on Revision of the Charter, to be appointed hereafter. On motion of DR. CHAMBERLAIN they were considered separately. The first one, as verbally amended and passed, was to the effect that all remarks in the scientific discussion of any paper may be committed to writing by the person making them. The second that each County Society designate at the time of election the one that is to act as a member of the Nominating Committee, and also appoint a substitute. It was also voted that the Secretary be a permanent officer, and that he shall receive a salary of fifty dollars annually, commencing with 1884. A salary of twenty-five dollars was also voted to the Treasurer. Heretofore the Secretary has received no compensation, and the Treasurer only a nominal sum, designed to meet certain expenses. The treasury is now in such a condition that some provision can be made where it is justly due.

The proposed amendment that no voluntary paper shall be read that has not been read before the State Society, or indorsed by some County Society, elicited considerable debate, and was finally tabled.

COMMITTEE ON REVISION OF THE CHARTER.

It was then voted that a committee composed of one from each County Society should be appointed by the President to consider the revision of the Charter, to report to a special session of the Society to be called by its chairman before the close of the next Legislature. This committee should also coöperate with the Corporation in securing farther legislation, should any be needed, to sever the relations now existing between the Society and the medical institution of Yale College. The President appointed on this committee Drs. C. W. Chamberlain, M. C. White, F. N. Braman, G. L. Porter, C. J. Fox, F. D. Edgerton, R. S. Goodwin, F. L. Dickinson.

THE RETIRING SECRETARY.

DR. WILE then presented the report of the committee appointed last year to draft resolutions of thanks to the retiring Secretary, who had filled the office for eight years. The report was accepted.

PUBLICATION OF TRANSACTIONS.

It was voted, on motion of PROF. M. C. WHITE, that the Secretary proceed to publish the Transactions of the Society previous to 1830, together with such papers read before it as can be obtained. That one thousand copies be printed, and a copy sent to each member of the Society.

The Secretary stated the estimated expense to be about three hundred dollars, and about two hundred and fifty dollars had been raised for this special purpose. Hartford and New Haven counties had each raised one hundred dollars; other counties had promised their proper share. In Hartford Dr. G. W. Russel had given fifty of the hundred raised.

HONORARY MEMBERS.

The Committee on Honorary Members proposed the following names to be acted upon next year: Dr. William F. Hutchinson, of Providence, R. I., and Dr. Morris H. Henry, of New York. They also presented the following names for action this year: Dr. James E. Reeves, of Wheeling, West Virginia, Secretary of the State Board of Health of that State, and Prof. T. A. Emmet, of New York, who were elected honorary members.

EXPULSION OF DR. E. L. R. THOMPSON.

The Committee on Resolutions from county societies reported that the steps taken by the New Haven County Medical Society in the expulsion of Dr. E. L. R. Thompson, charged with procuring an abortion, were in accordance with the rules of the Society, and recommended that their action be sustained, which was voted unanimously.

TREASURER'S REPORT.

The report of the Treasurer, DR. E. P. SWASEY, was then read, showing the expenses larger than usual, due to the unusual item of legal advice. The receipts were also larger, leaving the treasury in good condition. This, he stated, was due to the increasing membership to some extent, and the larger proportion of paying members, but principally to the zeal and earnestness of the county clerks, who are the collectors of the taxes. He urged that those in office should be retained as long as they will consent to serve, and upon

the clerks to retain their places, although laborious, as changes caused confusion and much extra labor. Of the tax of 1883 less than fifty dollars remains due. The report was referred to the auditors, and upon their report as correct, received and ordered on file.

As the reports of the Standing Committees on Examination and Nomination of Professors were not in readiness, they were ordered to be made to the Secretary as early as possible.

AMENDMENT TO BY-LAWS.

On motion of DR. CHAMBERLAIN the expediency of increasing the number of standing committees by appointing one on hygiene, one on surgery, etc., was referred as an amendment to the By-laws to the next convention.

ELECTION OF OFFICERS.

The Nominating Committee reported the following officers, who were duly elected: President, B. N. Comings, of New Britain; Vice-President, E. C. Kinney, of Norwich; Treasurer, E. P. Swasey; Secretary, S. B. St. John; Committee on Matters of Professional Interest, N. E. Worden, J. H. Grannis, E. A. Hill; Committee on Examination, F. D. Edgerton, H. W. Buell, Lewis Barnes; Committee to Nominate Professors at Yale Medical School, C. W. Chamberlain, G. L. Porter; Committee on Publication, I. W. Lyon; Committee of Arrangements, M. Storrs, W. M. Hudson, James Campbell; Dissertator, W. H. Holmes.

After the usual routine business the Convention adjourned to meet at the call of the chairman of the Committee on Revision of the Charter.

THURSDAY'S SESSION.

The Convention met promptly at nine A. M., with the President, Dr. Nye, in the chair, and Dr. St. John at the Secretary's desk.

HISTORY OF THE YEAR.

The first business in order was the SECRETARY'S report. He stated that the usual harmony and prosperity had marked the history of the year. The losses by death have been unusually small in number; but four. There has been one expulsion, and five have left the State. Forty-three new members have joined through the various counties, so that the Society now numbers 480. He gave an account of his work before the Legislative Committee with reference to the measure relating to the sale of patent medicines, and also of the memorial relating to the National Medical Library and Army Medical Museum, which had been sent to the members of the Senate and House. He had not commenced the publication of the early Transactions previous to 1830, as before this session all the county societies had not been heard from, all that had expressed a willingness to pay their share. One hundred dollars had been received from Hartford County, fifty dollars the gift of Dr. G. W. Russell. A like amount had been contributed by New Haven County. The expense would be about three hundred dollars, which would be fully met by a contribution of fifty cents from each member who had not already paid. That was the assessment in the counties thus far reported.

ADDRESS BY THE PRESIDENT.

The President's address, on The Claims of the Medical Profession to the Respect and Gratitude of the Community, is well described by its title. The sacrifices made by physicians for the public good, and their self-denying labors in investigating the causes and prevention of disease, their great work in securing proper treatment for the insane and the like, in advancing education and promoting reform, were clearly set forth, while the rewards from the public and the place given the physician in the conduct of affairs are far from commensurate with his work and its results.

The President-elect, DR. B. N. COMINGS, then took the chair. Reports of various committees were presented and properly referred. The delegates from other States were then presented, and made brief speeches: Dr. English, of New Jersey; Drs. Burdette and Richardson, of Massachusetts; Drs. Schwartz and Smith, of Rhode Island; Dr. Hammond, of New Hampshire, and Dr. Huntington, of Vermont.

MEDICINE FIFTY YEARS AGO.

A very interesting paper, full of personal reminiscences, was read by DR. MATHEWSON on Medicine Fifty Years Ago. The advent of the various instruments of precision were detailed in turn, and one account of the opposition they aroused, especially the whole department of gynæcology and its armamentarium. He described graphically the opposition to Tully because he denounced the lancet, and the distrust of the profession. Tributes were also paid to Nathan Smith and Benjamin Silliman. Yale then had the largest class of any medical school in New England, although Harvard graduated a few more.

THE TREATMENT OF STRANGULATED HERNIA

was very well treated by DR. HARRIS, and the results of seventy-five cases of all grades of conjunctivitis treated either by cleanliness alone or by the use of antiseptics, mainly boracic acid, given by Dr. Wilson.

PRESENTATION OF CASES.

The presentation and relation of interesting cases was then called for.

PROFESSOR CARMALT related a successful case of litholapaxy in a man forty-two years old. Ninety-seven grains of calculous matter were removed; the patient went home in four days, having had no fever. An attempt at wiring the patella for ununited simple fracture rebroken, or rather torn apart by accident, resulted unsuccessfully, the wire cut through the upper fragment in trying to pull it down. Necrosis followed, free drainage was established, and suppuration did not extend into the joint. He did not think well of the operation, and had collected statistics of thirty cases, failure resulting in fifty per cent.; death from pyæmia had been caused. He also exhibited two patients, one of extirpation of the tongue for cancer; the lingual arteries were first tied, so the operation was bloodless; tracheotomy had also been performed. The patient could talk well.

The second was subfenestral section of the femur to obviate ten inches shortening, from former hip-joint disease, but two inches were left, and with a shoe she could walk quite well.

A very lifelike drawing of a syphilitic eruption and ulcerating condylomata, drawn and colored by Dr. Leighton, was presented by Professor Beckwith, who related the history of the case; oleate of mercury locally, and mercury internally, effected a cure; he preferred mercury to the iodide of potash.

DISSERTATIONS, PAPERS, AND SPEECHES.

PROFESSOR BECKWITH urged the claims of the Sims Memorial upon the Society, and reported what had been done in several cities of the State.

The dissertation upon the Germ Theory of disease was then read by Dr. Worden. An able presentation of all known upon the subject up to the latest utterances. It was exhaustive and thorough, and claimed the close attention of all until its close.

The early recognition of Potts' disease was urged by Dr. Packard, and the mischief caused by delay, often irremediable, clearly portrayed. He advocated fixation by a plaster-of-Paris support.

DR. BEARDSLEY gave a more detailed account of his method of treating all forms of malaria without quinine. His remedies were an aloetic or mercurial purgative, or preferably a combination of the two with capsicum, until bilious stools were produced; arsenic with serpentaria, anise, caraway, fennel, and a bitter tonic, gentian, or his favorite boneset tea *ad libitum;* salicin and rhubarb he also used, claiming good results where large doses of quinine had failed.

After miscellaneous business and reading other papers by title, the Society adjourned for dinner, where Mayor Lewis, President Porter, of Yale, Clarence Deming, Professor Bunce, Dr. Delevan, of New York, Dr. English, of New Jersey, and others, made pleasant and entertaining after-dinner speeches.

AMERICAN NEUROLOGICAL ASSOCIATION.

TENTH ANNUAL MEETING. HELD IN NEW YORK JUNE 18, 19, AND 20, 1884.

FIRST DAY. AFTERNOON SESSION.

ANNUAL ADDRESSES.

THE Vice-President, DR. WILLIAM J. MORTON, of New York, occupied the chair, and having read a letter of regret from the President, Dr. Robert T. Edes, of Boston, who was unable to be present, made an address in his place, which was devoted to a retrospect of the work of the Society, and to a defense of specialism, particularly in the department of neurology. At the conclusion of it he introduced the President-elect, DR. ISAAC OTT, of Easton, Penn., who delivered the President's address, the subject of which was The Paths of the Various Fibres in the Spinal Cord. After reports had been made by the Council and by the Secretary and Treasurer, Dr. R. W. Amidon, the annual

ELECTION OF OFFICERS

took place, and resulted as follows: President, Dr. Burt G. Wilder, of Ithaca, N. Y.; Vice-President, Dr. Leonard Weber, of New York; Secretary and Treasurer, Dr. Graeme M. Hammond, of New York; Councilors, Drs. W. R. Birdsall and William J. Morton, of New York.

RARE SPECIMENS.

PROFESSOR WILDER then exhibited the following:—

Preparations illustrating (*a*) the existence and circumscription of the portæ (foramen Monroi) in the adult human brain; (*b*) the presence of the crista fornicis in fœtal and new-born human brains; (*c*) the covering of the cerebellum by the cerebrum in a young chimpanzee whose brain was hardened within the skull.

He also stated that he had collected two additional instances of absence of the callosum in the domestic cat, the specimens of which he had, unfortunately, neglected to bring with him.

DR. AMIDON then exhibited a human brain in which the corpus callosum was absent.

FIRST DAY. EVENING SESSION.

ELECTION OF NEW MEMBERS.

The following new members were elected: Dr. Sarah J. McNutt, of New York; Dr. G. Belton Massey, of Philadelphia; and Dr. George W. Jacoby, of New York.

THE REPORT ON THE HAMMOND PRIZE ESSAY

on the Functions of the Optic Thalamus in Man was read by the SECRETARY, and in it it was stated that but one essay had been received, and that although it was possessed of remarkable merit, in general the committee had decided not to award the prize to it, for the reason that the portion of it relating to the special functions of the optic thalamus in the human subject was scanty and inconclusive.

The first paper of the evening was read by DR. BURT G. WILDER, of Ithaca, on

MACROSCOPIC ENCEPHALIC NOMENCLATURE,

in which he advocated the introduction of a new system which substituted simpler names for many of the terms now in use; claiming that the monomial technical nomenclature which he proposed possessed the following advantages: (1) brevity; (2) flexibility; (3) adaptability; and (4) capacity for uniform abbreviation.

DR. A. D. ROCKWELL read a paper entitled

A CASE OF TONIC SPASM OF THE DIAPHRAGM (?).

The patient was a lady thirty-five years of age, who had been the subject of severe paroxysms of distress for twelve years. In these she was awakened out of a sound sleep by a feeling of oppression about the lower end of the sternum and over the epigastrium, and extending also to a corresponding point in the back. She described it as resembling the application of a crushing weight, as if the front and back were being pulled together. The recumbent position was impossible, and so she moved about the room partially bent, or leaned forward against some support, with short and gasping inspirations, with pallid countenance, and with agony depicted in every feature, until the paroxysm subsided, or until the anguish became unendurable and necessitated the administration of an anæsthetic. The attacks lasted from twenty minutes to three quarters of an hour. Before the present year they seldom occurred more than once a year, and sometimes two or three years intervened between them. During the months of April and May past, however, they had been very frequent; usually occurring once every day and occasionally twice a day. When the attacks became thus frequent electricity was tried in all its forms, together with a varied internal treatment, but without result. Finally the actual cautery was applied to the spine, from the neck to the waist, and since this had been done (now about a month since) the patient had been entirely free from the paroxysms. Having referred to other possible hypotheses in regard to the cause of the trouble, such as biliary calculus, disorder of the heart, and malaria, Dr. Rockwell stated his conviction that the attacks were in all probability due to spasm of the

diaphragm, notwithstanding the absence of certain objective symptoms, such as expansion and immobility of the lower half of the chest, projection of the epigastrium, and closure of the œsophagus, that he had found emphasized in the books.

The discussion of the case was participated in by a number of members, some of whom were unwilling to accept Dr. Rockwell's view of it, although no positive conclusion could be reached in regard to it.

DR. BIRDSALL thought that it might perhaps be due either to hysteria or to hepatic colic.

(To be concluded.)

RHODE ISLAND MEDICAL SOCIETY.

THE Seventy-third Annual Meeting was held in Lyceum Hall, Providence, June 19, 1884. The President, DR. JOB KENYON, called the meeting to order shortly after ten o'clock A. M.

REPORTS OF SECRETARY AND TREASURER.

The SECRETARY read the Records of the Annual Meeting of 1883, and of the last Quarterly Meeting. The Annual Report respecting the membership of the Society was then read, which showed that four Fellows died during the past year, their average age being sixty-two years. There were nine additions, the present active membership being one hundred and eighty-seven.

DR. CHARLES H. LEONARD, Treasurer, presented his annual report. The income for the year, including the balance from the old account, was $983.02. Outgo, $764.14. Balance to new account, $218.88.

The Printing Fund increased during the year to $1533.43, to which the Society voted to transfer $200 from the unexpended sum in the treasury.

THE FISKE FUND.

DR. C. W. PARSONS, Secretary of the Trustees of the Fiske Fund, reported that a premium of $300 had been awarded to CHARLES V. CHAPIN, M. D., of Providence, for the best essay on the Origin and Progress of the Malarial Fever now Prevalent in New England. On the other subject proposed they make no award.

The Trustees propose the following subjects for 1885: —

(1.) Original Investigations in Household Hygiene.

(2.) The Present State of the Germ-Theory of Disease.

(3.) Physiological and Pathological Effects of the Use of Tobacco.

(4.) Migraine, its Nature and Treatment.

For the best dissertation on either subject worthy of a premium they offer a prize of $200.

REPORTS ON THE LIBRARY AND ON PUBLICATIONS.

DR. T. NEWELL, Chairman, presented the Fifth Annual Report of the Committee on the Library, exhibiting the gratifying increase of 1086 volumes during the year. The library is open daily at 54 North Main Street from two to six P. M.

DR. G. W. PORTER read the Annual Report of the Committee on Publications. The Transactions for the year 1883 is considerably smaller than for several previous years, partly because there were fewer papers presented to the Society during the year, and partly because some of the readers declined to furnish their papers for publication.

ELECTION OF FELLOWS.

DR. J. W. C. ELY read the Report of the Board of Censors, and as recommended by the Board the following physicians were elected Fellows: Henry S. Swan, of Bristol, Abraham Z. Falcon, of Central Falls, William A. Tremaine, Byron J. Lillibridge, Sanford S. Burton, and Benjamin R. Symonds, of Providence.

LEGISLATION. MEETINGS OF OTHER SOCIETIES.

DR. LLOYD MORTON, on behalf of the Committee on the Medical Examiners' Bill, reported that the bill adopted at the last Quarterly Meeting of the Society had been passed in a modified form by the General Assembly of Rhode Island. The act as passed takes effect on the first day of July, 1884.

DR. J. H. ELDREDGE read a Report of the Thirty-Fifth Annual Meeting of the American Medical Association lately held in Washington.

DR. ANITA E. TYNG, of Philadelphia, sent a report of the same meeting, with special reference to the work of the Section on Obstetrics.

DRS. ARIEL BALLOU and W. E. ANTHONY also reported verbally.

DRS. F. B. SMITH and G. T. SWARTS presented reports of the Annual Meeting of the Connecticut Medical Society.

The President introduced DR. C. HOWE, of Taunton, as a delegate from the Massachusetts Medical Society. DR. HOWE responded pleasantly.

ELECTION OF OFFICERS.

Officers for 1884–85 were elected as follows: Oliver C. Wiggin, President; Horace G. Miller, First Vice-President; John W. Sawyer, Second Vice-President; George D. Hersey, Recording Secretary; Edward M. Harris, Corresponding Secretary; Charles H. Leonard, Treasurer. Censors: Ariel Ballou, J. H. Eldredge, J. W. C. Ely, G. P. Baker, S. S. Keene, Benjamin Greene, E. T. Caswell, Eugene Kingman. Committee on the Library: T. Newell, H. G. Miller, G. D. Hersey, O. C. Wiggin, G. W. Porter. Committee on Publications: G. W. Porter, R. F. Noyes, C. D. Wiggin. Dinner Committee: C. H. Leonard, W. E. Anthony. Auditing Committee: C. W. Fabyan. Dr. Lloyd Morton, of Pawtucket, was appointed Anniversary Chairman for the annual meeting of 1885. The President appointed as a Committee on Necrology, Drs. C. W. Parsons, E. T. Caswell, and Albert Potter. Providence was selected as the place of the quarterly meeting in September.

DECEASE OF DRS. BULLOCK AND PERRY.

DR. W. E. ANTHONY, from a committee appointed at the last meeting, presented the following minute, which was accepted and ordered recorded: —

Whereas, In the decease of DRS. OTIS BULLOCK and THOMAS W. PERRY this Society has lost two members who had long been connected with it:

Resolved, That we desire to place on record our appreciation of those traits of character by which they had attained a position of honor and usefulness in the Society and community. Dr. Bullock was for one year President of the Society, and for forty years was a member of the Board of Censors, and, as such, conscientiously fulfilled all the duties pertaining to the office with unfailing kindness and courtesy.

Dr. Perry was a frequent attendant on our meetings

and often contributed the results of his large experience to the discussions.

Resolved, That these resolutions be entered on our record and a copy of the same be sent to the families of the deceased.

ANNUAL ADDRESS. DINNER.

At one P. M. the Annual Address was delivered by George I. Chace, LL. D., his subject being Theism, Viewed from the Physician's Stand-point.

At the close of the address the thanks of the Society were voted to Professor Chace for his thoughtful and timely discourse, and a copy requested for the archives of the Society.

The Annual Dinner was served at the Narragansett Hotel. Dr. J. W. C. Ely presided as Anniversary Chairman. After-dinner speeches were made by ex-President Kenyon, President-elect Wiggin, Professor Chace, Rev. Dr. Woodbury, Prof. Alonzo Williams, Dr. Ariel Ballou, and Dr. Charles E. Woodbury, Superintendent of Rhode Island Hospital.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.

W. H. TAYLOR, RECORDING SECRETARY.

The seventh annual meeting, at the rooms of the Boston Medical Library Association, June 10, 1884, was called to order at 12.05 P. M. by President Presbrey, twenty-one members being present. The records of the last meeting were read and approved. The President introduced Associate Member Max F. Eller, Esq., of New York, to the Society.

REPORTS.

Corresponding Secretary Pinkham made the report of the Executive Board, showing the work of Medical Examiners throughout the State as far as the account of it can be obtained. Medical Examiner Tower, the Treasurer, made his report, showing the financial condition of the Society.

ELECTION OF MEMBERS.

Medical Examiners Frank W. Pierce, of Marston's Mills, Julian A. Mead, of Watertown, and Justin G. Hayes, of Ipswich, were unanimously elected to active membership. Drs. Alfred Hosmer, of Watertown, and Y. G. Hurd, of Ipswich, were unanimously elected to active membership.

Voted, on motion of Medical Examiner Pinkham, that numbers of the last Transactions be sent to medical examiners not members of the Society who have contributed to statistics.

THE LAW OF MEDICAL EXAMINERS.

The committee to "consider the Law of Medical Examiners," etc., made a report, and offered some amendments to the present law.

Voted, on motion of Medical Examiner Pinkham, that the report be laid upon the table until the meeting of the Society in October.

Voted, on motion of Medical Examiner Lynde, that the proposed amendments to the law of medical examiners be printed and distributed to members of this Society before the October meeting.

PRINTING THE TRANSACTIONS.

Voted, upon motion of Medical Examiner Draper, that an edition of three hundred copies of the Transactions for the current year be printed.

Voted, upon motion of Medical Examiner Draper, that authority be given to the Standing Committee to publish in the appendix of the Transactions such medico-legal reports contributed by members of this Society and printed in the *Boston Medical and Surgical Journal* as the Committee may deem expedient.

ELECTION OF OFFICERS.

Proceeding to ballot, Medical Examiner S. D. Presbrey was elected President, Medical Examiner F. Winsor Vice-President, Medical Examiner J. G. Pinkham Corresponding Secretary, Medical Examiner W. H. Taylor Recording Secretary, Medical Examiner C. C. Tower Treasurer for the ensuing year. Medical Examiners Draper, Gleason, and Sullivan were appointed Standing Committee for the ensuing year.

READING OF PAPERS.

Max F. Eller, Esq., of New York, read a highly interesting and valuable paper on A Few Medico-Legal Features of Life Insurance.

Voted, on motion of Medical Examiner Draper, that the thanks of the Society be extended to Mr. Eller, and that his manuscript be requested for publication.

Papers were read by Medical Examiner F. W. Draper on A Case of Homicide by a Wound of the Vulva, with Specimen; by Medical Examiner S. D. Presbrey, entitled Notes of two Autopsies; and by Medical Examiner George Stedman on A Case of Drowning. The papers were all of great interest, and were received with applause by the Society.

Recent Literature.

The Laws of Health. By Joseph C. Hutchison, M. D., LL. D. New York: Clark & Maynard. 1884.

This is an elementary text-book upon physiology and hygiene, the object of which, as stated in its preface, is "to present, in clear and concise language, the knowledge of to-day concerning the laws of health and the effects of narcotics and stimulants as far as possible in a work so elementary. It is specially designed to meet the requirements of grammar schools, but is also adapted to those of a higher grade."

The physiological effects of the habitual and the occasional use of stimulants and narcotics are treated in connection with the chapters on Food and Drink, Digestion, Circulation, and the Nervous System.

Humanitarians, organized workers, legislators are untiring in their efforts to stay the progress of intemperance by various methods, some of which are well advised and others ill advised, but the more recent proposal of educators to remedy the evil by the early training of the child gives promise of better results.

The prevention of an evil by correct education in early life is a more encouraging process than its cure by any treatment, either mild or heroic, in later years, and the timely appearance of this text-book by Dr. Hutchison is well calculated to meet the demand for such elementary instruction as it contains.

Medical and Surgical Journal.

THURSDAY, JUNE 26, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,

THE TUBERCLE BACILLUS.

IT is natural that pathologists, impressed by the specific character of tuberculous disease and its ready inoculability, — with, moreover, facts before them proving the infectious properties of dried tuberculous sputum when inhaled by animals, — should early have come to the conclusion that tuberculosis is a communicable disease, having generic and pathogenetic affinities with the zymotic contagious diseases, being dependent like them for its origin and manifestations on a self-multiplying element foreign to the organism in which it exercises its irritant and lethal influence. But what might this causal element be? a chemical poison impregnating and oppressing the system, or a microbe, akin to the moulds, intruding itself into the higher life, and finding there a receptivity — pullulating, developing, and luxuriating at the expense of the organism which becomes its habitat? All the evidence of analogy is against the former supposition, and there is every analogy in favor of the latter, but experimental research has given demonstration of a more satisfactory kind.

Leaving one side the history of investigations undertaken to establish the bacterial origin of acute febrile diseases universally recognized as communicable, a history almost dating from Pasteur's Studies on Fermentation, and the brilliant discoveries of Devaine and Ferdinand Cohn, it is to Villemin that is due the credit of having first clearly indicated the contagious nature of tuberculosis, and its inclusion among parasitic diseases. Villemin's views were based on the results of inoculations of guinea-pigs and rabbits with minute quantities of tuberculous matter, and the communication and diffusion of tuberculosis thereby. The memoir of Villemin was published in 1865. Facts were even then accumulating to show the parasitic origin of all contagium, but the specific bacterium of no single infectious disease had been positively determined. Villemin boldly asserted the parasitic origin of tubercle, and showed how strikingly in harmony is this conception of the disease with the doctrine, formulated by Laennec, and then becoming popular, of the unity of phthisis.

Dating from the year 1877, several experimenters, notably Klebs, Schuller, Reinstadler, Toussaint, believed that they had discovered the parasite of tuberculosis, and practiced inoculations with the microbe to which they attributed the disease. Their inoculations were without effect, the bacteria which they had isolated being only common bacteria. The same may be said of the micrococcus and the corpuscles called zoöglœ which were found in the giant cells of tubercle by Rindfleisch, Aufrecht, Malassez, and others. The 24th of April, 1882, Dr. Robert Koch, of Berlin, demonstrated to the Medical Society of that city a new micro-organism of rod-like form, belonging to the genus bacillus, characteristic in its chemical and morphological properties and effects, which he claimed to be the true pathogenic and virulent agent of tuberculosis. Koch arrived at the discovery of this microbe by a peculiar process of staining which, as somewhat modified and improved by later workers, consists in coloring the morbid substance by aniline, then subjecting the preparation to the action of dilute nitric acid, which decolorizes all the figured elements except the bacillus. The section is finally colored anew in vesuvine, which stains all the other microbes blue, the tubercle bacilli alone retaining the brown color acquired from the aniline. Thus obtained the bacilli appear as very thin rods, whose length is about one fourth that of a blood corpuscle.

It is probable that no announcement ever made a profounder sensation in the medical world, or was received with more enthusiasm. Here was a field of investigation for the mycologists and the pathological histologists of which they were not slow to take possession. The first demonstration of the ætiological relation of the bacillus to tubercle is concomitance; if invariably and always the microbe is found to accompany the disease, the presumption is warranted that it is the cause, though it may be the effect. The first step, then, to prove a causal relation is to prove the constant presence of the specific parasite in tuberculous tissue, or in the products of tubercle. This, the easiest part of the demonstration, within the reach of even the amateur microscopist, has been quite thoroughly worked out.

In a prize essay recently read before the French Academy of Medicine the author, M. Herard, sums up as follows an answer to the question "Is the bacillus *constant?*" "The researches, to-day very numerous, of competent histologists in every land agree in this: The bacilli are found, with very few exceptions, in all the products of the excretions of a tuberculous organ, and notably in the sputa of phthisical patients. Constantly, or almost constantly, they are observed in the divers tuberculous lesions; yet while in certain cases the quantity of bacilli is considerable, and they are found in all the lesions, whatever the stage of evolution of the disease, in other cases the number is small, and they are seen in greatest abundance in the young granulations, and especially in the centre of the granulations in the giant cells. When the bacilli are wanting in the parts that have undergone caseous degeneration they are generally met with in abundance in the surrounding zone which contains the granulations recently developed. Sometimes the bacilli are only found in the walls of cavities or of ulcerated bronchi, and there they are very numerous." The bacilli then, according to M. Herard, exist in variable number according to the degree of evolution of the

lesions; abundant in the earlier stages when the tuberculous development is active, they are less and less numerous as destruction and elimination take place, and the soil becomes, presumably, less fitted for their nurture and support. In later periods of the disease other microbes — those of putrefaction — seem to acquire predominance.

With regard to the few exceptional cases where the bacilli have not been found it is safe to say, according to M. Herard, that either the disease was past the stage of active development of the specific microbe or that the manipulations undertaken to show them were not sufficiently exact.

Granting constant concomitance, is it not possible that Koch's bacillus may accompany other lesions than those of tuberculosis? The voice of the experts thus far negatives this question. The bacillus is not found in any pulmonary affections except such as constitute phthisis, and its presence becomes a very valuable diagnostic sign. Some authorities, among whom we may mention Germain Sée, Dreschfeld, Celli, and Guarnerini, would hesitate to pronounce a diagnosis of phthisis in the absence of the specific bacillus from the expectoration. Sée claims to have diagnosticated phthisis by the bacillus in the sputum before the stethoscopic signs were sufficiently pronounced to warrant affirmation of the existence of the disease.[1] But concomitance alone proves nothing; the bacillus must be shown to be the cause and not the effect, nor even an unimportant accompaniment. Here two lines of evidence are open: production of the disease by inoculation with the microbe, and suppression of the disease by removal of the microbe. The former line of proof is alone available at present to experimental pathologists. It must be confessed that in this department of inquiry but little has as yet been done. Were it not for Koch's brilliant success in the culture of the bacillus, after Pasteur's method, a method, however, differing from that of Pasteur in that Koch, after many trials and failures, found that a solid medium (gelatinized blood) was every way more favorable for the perfect isolation and development of the microbe than the ordinary liquid media; were it not, moreover, for the positive results which he obtained from inoculations with the bacterial product of a long series of cultures, thus demonstrating the genesis of tubercle from a figured element alone, it could not yet be affirmed that the parasitic theory of tuberculosis stands on a substantial scientific basis. Those, moreover, who are not willing to accept Koch's experiments as conclusive, or who still believe that these experiments were in some yet unexplained way vitiated by error, will look for more proof before they are convinced. It is true that such conscientious experimenters as Baumgarten[2] have demonstrated that tubercle owes its virulence and its contagium to the presence of bacilli by showing that granular and caseous matter, phthisical sputa, etc., when inoculated in animals, does not engender tubercle if previously deprived of its bacteria. This is excellent confirmatory evidence, but we still await the more important corroborative testimony of mycologists who shall have followed Koch's method and obtained the same results.

"Truth never can be confirmed enough,
Though doubts did ever sleep."

Finally, in this whole matter of tuberculous ætiology, predisposition plays an important part. Not every man or animal can become tuberculous, and the soil must be adapted to the parasite or it cannot find a habitat and thrive. There must be a peculiar receptivity either inherited or acquired. This susceptibility of constitution and of tissue, then, constitutes the initial step in the genesis of tuberculosis, and it is against this predisposition that prophylactic medicine is mainly directed. The condition of organism most favorable to the inroads of the parasite is one of lowered vitality, with the pulmonary alveoli unprotected by epithelium, a condition likely to follow a severe catarrh. Here the bacilli find ready access to the lungs in the air of respiration, and, unless the vital resistance of the economy can be aroused to overcome them, do their work of destruction.

We do not attempt at present even to refer to the light which the parasitic theory of tubercle sheds on the unity of scrofulosis and tuberculosis and of the varied forms of phthisis.

REPORT OF CASES TREATED IN WARD XIX. ROYAL INFIRMARY, EDINBURGH.

Nowadays the records of abdominal surgery are in general very cheerful reading. They have many of the elements of romance, and one rises from perusing them with a thrill of excitement quite as great as that which one experiences from reading an exciting tale of adventure. There is the deadly peril hanging imminent over the unfortunate victim, who is a prey to suffering and despair, the desperate venture, the hair-breadth escape, the alternation of hope and fear, the final victory over the dread disease, and the restoration to health of one doomed to die.

This makes a very bright page in the history of medicine, and the sense of exhilaration is surprisingly vivid when fresh from reading such a series as that contained in the Report of Cases Treated in Ward XIX. of the Royal Infirmary, Edinburgh, by Thomas Keith. The number is not large, only seventy-nine, but it represents the work of about three years in that institution, in this one direction. There seems to have been in this number an unusually large proportion of what would be considered desperate cases. There were ten cases of hysterectomy for fibrous tumors, and sixty-nine of ovariotomy. Only thirteen of the cases of ovariotomy were without adhesions, and but two of the cases of hysterectomy could be called simple. Yet the mortality was slight, five deaths in all; two from undoubted septicæmia, two from carbolic-acid poisoning, and one probably from exhaustion.

It is interesting to notice Keith's attitude towards pure Listerism, so-called. Of eighty-two cases of abdominal section (two cases of Battey's operation, and one for interstitial pregnancy being included), twenty-

four were done under carbolic-acid spray, with four deaths, two under boro-glyceride spray with one death, and fifty-six without spray with but one death. He therefore says: "The performing of operations under carbolic spray has been abandoned as being of doubtful efficacy in preventing septicæmia, and as sometimes being in itself a source of danger in certain long operations, and in some conditions of the constitution."

We do not propose to discuss methods of operation. The questions of spray or no spray, ligature or cautery, extra or intraperitoneal treatment of the stump, drainage or no drainage, must be decided according to the individual experience of the operator. We are yet in the infancy of abdominal surgery, and have not yet proven all things, to know what we may hold fast.

But certain reflections involuntarily occur after reading such a report as the one before us. There is evidence of a strong conscientious desire to relieve suffering humanity, even at the risk of spoiling a good record. The most hopeless cases were given the chance, even though it was a last resort, and we are led to feel that almost no combination of circumstances, however unfavorable, warrant a refusal to operate.

Accuracy of diagnosis is of primary importance in abdominal surgery. When the incision is made, not for the purpose of exploring, but of carrying out quickly and thoroughly what has been determined upon before hand as the thing to be done, the surgeon has won half the battle.

From the report of Keith's cases it is easy to see that he deprecates meddlesome interference after operation. He trusts largely to the *vis medicatrix naturæ*, and does not with heroic measures combat symptoms which to us seem unfavorable, but which may after all be nature's method of averting some more grave issue.

It cannot be said that the operations described in this report were performed under the most favorable circumstances, and yet the results were exceedingly satisfactory. We will hope that the next report will be yet more encouraging.

MEDICAL NOTES.

— Dr. Wilson, of Louisville, has used with success the inner membrane of a hen's egg for skin-grafting. One egg will supply an indefinite number of grafts.

— A paper in the *London Medical Times* (March 8th) condemns the wholesale removal of tonsils for chronic inflammation. The disease is peculiar to certain individuals, usually those of a strumous type. In many cases other lymphatic enlargements coexist. The cause of the fluctuation in size in the same person, and of the regrowth after removal, is to be looked for in the anatomy of the organ. It is made up entirely of lymphatic and adenoid tissue. The symptoms produced are the peculiar expression of the face, the noisy breathing at night, occasional deafness, and less frequently abdominal pain and capricious appetite. So long as deglutition and respiration are not interfered with the size of the tonsils is usually a matter of little importance. A strong tendency to atrophy as age advances exists. When the tendency to hypertrophy is still present it is almost certain to show itself after ablation. The general, not the local, condition should be aimed at as the object of treatment. In most cases it is found that cod-liver oil and iron will do as good work before as after operation. Except for the one cause of local obstruction there is no more reason for removing hypertrophied tonsils than any other enlarged lymphatic glands.

— "Jacob the Zouave," formerly a private in a French regiment of zouaves in Algeria has been making himself a prominent figure in Paris of late. He had acquired some facility as a mesmerist, and, returning to Paris, set up for himself as a healer is no less a quarter than the Champs Elysées, where patients of the highest ranks thronged his cabinet. To keep within the letter of the law he asked for no fees, but insisted on selling his portrait to every patient, the resulting income amounting to some fifty dollars a day. He has found it convenient to remove at frequent intervals from one part of the city to another, but his refined clientèle, as a class, if not as individuals, still attend him.

Correspondence.

MATERIA MEDICA AT THE HARVARD MEDICAL SCHOOL. LETTER FROM PROF. R. T. EDES, M. D.

BOSTON, *June* 19, 1884.

MR. EDITOR, — I am much pleased that the JOURNAL appreciates at its true value the excellent and admirable collection of materia medica in the new Museum of the Harvard Medical School.

I regret, however, that you do not give credit to Dr. W. P. Bolles for the great amount of labor he has spent upon it, but also for the arrangement, upon which you justly comment approvingly, which is, so far as I know, his own in conception and carrying out.

I am, yours truly,

ROBERT T. EDES.

LETTER FROM VALPARAISO.

VALPARAISO, CHILI, *May* 7, 1884.

MR. EDITOR, — As a requisite for professional standing and right to practice in Chili a medical man, no matter from what University he brings a degree, is required by the government to pass an examination before the Faculty of the Medical Department of the University of Chili. The degrees which are recognized, and those of Harvard University are among the few from the United States which are accepted, entitle one to be considered a "licentiate," and therefore a practical examination is all that is required of one presenting such a diploma. This consists in the examination and diagnosis of two medical and two surgical cases before a board of five of the professors, the per-

formance of a couple of operations on the cadaver, and, lastly, a public *viva voce* examination lasting from an hour and a half to two hours, with special reference to the cases seen. The questions, however, are by no means limited to the cases in hand, but extend over a wide range, touching on pathology, therapeutics, theory and practice, surgery, gynæcology, obstetrics, and prescription writing.

The hospital where patients were seen and examined is one devoted entirely to men. It was founded in 1542 by Pedro Valdivia, Pizarro's lieutenant, who in 1541 chose one of the most fertile and beautiful valleys of the country for the site of Santiago. The hospital is built in squares, which have broad balconies running all around the inside, so that patients during convalescence have no lack of out-door life, which can be enjoyed almost the whole year round. In its sanitary arrangements, the quality of food, the nursing of patients, the use of temperature charts, and keeping of records there is much advance yet to be made; but the general arrangement of the institution is good, and well suited for the clinical instruction given. In one way this is advantageously conducted, and that is that students are assigned cases, and have to study them and give their results before the class and instructor, at the bedside. In one ward I saw two cases of an affection but rare in the United States, namely, abscess of the liver. It is quite prevalent here, as one frequently hears of the aspiration of such cases. As a rule it appears as a sequel to dysentery, which also prevails, and is supposed to be due often to the eating of a preparation of pork, with about an equal quantity of red pepper. When this active irritant is followed by the favorite popular spirit aguardiente, fire water, it is thought sufficient explanation of attacks of sporadic dysentery. In fact, popular tradition warns the people to refrain from piling Pelion on Ossa in this way. Some day I hope to be able to report some cases of this disease.

The one word which is said to characterize these South American people is "mañana," to-morrow. In attempting to be received here one is made painfully aware of this procrastination. Much patience is needed, and one may count himself fortunate if he has a day assigned him within six weeks of his first making application. Some claim that the theory of protection is here extended to shield native medical talent. This I do not believe, but rather recognize the merit of a system which seeks to prevent ignorance from clothing itself in a title, and bringing discredit on the profession and injury to the public. Certainly there was no evident intention of excluding one whose education had been obtained abroad. The examination, of course, is in Spanish. It was calculated to test one's theoretical and practical knowledge, but while rigid was perfectly square and straightforward.

During the oral examination I was struck by hearing quite a hum, among the students present, when, speaking of rapid dilatation for organic stricture, I spoke of administering ether. Here ether is practically unknown, the only anæsthetic used or spoken of being chloroform. My morning's experience at the Charity Hospital of this city, where I was present and assisted in a couple of operations, may not be without interest. One was a young woman with caries of a metatarsal and cuneiform bone, to whom I administered chloroform. The patient had previously been operated upon and taken the anæsthetic nicely. This time all went well for a few minutes, — aspect, breathing, and pulse good, — when suddenly respiration ceased. With artificial respiration the patient shortly cried, and began to breathe. The removal of the carious bone being desired, the chloroform was again applied, as previously, on Esmarch's wire and gauze apparatus, though cautiously. The pulse was good, aspect and breathing natural, but being administered very slowly the patient did not readily succumb to its influence. As soon as the conjunctival reflex ceased I reported being ready for the operation, but immediately the respiration again ceased. The patient was placed on the side of the table, head hanging down, tongue withdrawn, and artificial respiration performed for some minutes without effect. The battery was then procured and applied, and we had the satisfaction of witnessing the return of the rhythmical abdominal and thoracic movements. The operation was continued without further anæsthetic, one fourth of a grain of morphia being injected subcutaneously.

From the woman's ward we proceeded to the soldiers' quarters on the hill to witness a resection of the tibia. This case, too, had been operated on before, and with chloroform, when a section of bone four inches long had been removed. A couple of sinuses had remained open, and now the probe touched loose necrosed bone. The patient was apparently taking the chloroform well, and was soon limp. Remembering the morning's events, one of the attending surgeons advised the withdrawal of the anæsthetic. It was done, but at that moment a peculiar pallor came over the patient's face, and all respiratory movements ceased. The operator had been watching the pulse, and just moved to the foot of the bed. I stepped forward, and, taking the wrist, could not assure myself of any pulse. The head was immediately lowered, tongue withdrawn, abdomen and chest slapped with a wet towel, ammonia injected subcutaneously, artificial respiration continued for twenty minutes, and the battery used to stimulate the phrenic nerve, but without avail. There was no pulse or cardiac impulse at any time after noting the sudden change in the patient's condition, and respiration could not be restored. In the first case, both times, the respiratory movements ceased without any warning, while the cardiac contractions continued. In this case artificial respiration, performed according to Sylvester's method, and stimulation of the phrenic nerve restored breathing; whereas in the second case, again without any warning, the aspect betokened syncope, and both cardiac and respiratory contractions ceased together, and in this nothing availed to save life.

At the Boston City Hospital an almost daily experience with ether for twelve months showed that it had dangers, but fortunately they gave warning of their approach, and could be guarded against, beginning stertorous breathing or lividity warning one to desist, and never did I see any unfortunate result. Since settling here I have probably seen fifteen or twenty operations with chloroform, and in two of those have witnessed sudden collapse, which proved fatal in one.

The United States man-of-war Shenandoah anchored in our harbor a few days ago, and the daily papers reported her having yellow fever on board, but as her boats can be seen going to the landing the rumor must have been false. JOHN TRUMBULL, M. D.

P. S. May 8th. At an autopsy of the case reported no abnormality about the heart or its valves was detected; and examining the woman the area of cardiac dullness and heart sounds were found normal.

Miscellany.

A CASE OF EXTRA-UTERINE GESTATION. DELIVERY OF A LIVING CHILD PER VAGINAM. REMOVAL OF PLACENTA. RECOVERY.

THE following unusual case was recently reported to the Obstetrical Society of London by Dr. Mathieson, of Ontario.[1] In spite of the success of the operation in this particular instance, the general opinion of the Society was strongly against the vaginal operation, compared with abdominal section in such cases: —

The patient was aged thirty, the mother of five children. In November, 1880, menstruation (which had been regular, though scanty for two months) ceased, and abdominal pain began. In December, 1880, a lump was noticed low down in the left inguinal region. She was first seen by the author in March, 1881, when she had a tumor rising to the level of the navel, filling the left vaginal region and extending two inches to the right of the middle line. The uterus could not be mapped out. The sound passed three and a half inches, slightly to the right side and in front of the tumor. There was occasional pain in the tumor, tenderness, and a feeling "like jelly moving" which made her feel sick; painful micturition, irregularity of bowels. The tumor continued to enlarge, fœtal movements became stronger, and the pain more severe. On April 12th she had an attack of pain and nausea, with pulse 146, temperature 103.6° F., cold extremities and cold sweat; relieved by morphia. A similar attack occurred on April 23d, another on May 2d, and another about May 18th. On June 2d a somewhat similar attack was accompanied by pretty regular labor-like pains, independently of fœtal movements, and accompanied by a red discharge. The tumor continued to grow, and the most rapidly growing part was always the most painful. On June 13th occurred another attack like the last, but the pains were bearing down, though no bulging during them could be felt per vaginam. On June 28th she had a very severe attack of pain during micturition, followed by attacks of syncope. The roof of the vagina was filled with a doughy mass, solid on deeper pressure. Operation per vaginam was at once decided on, and performed without chloroform at the patient's request, by cutting with a knife and tearing with the finger nail. The face of the child was found presenting, and was delivered by forceps easily. It was stillborn, but soon revived. The placenta was at the posterior and left side of the cavity, its lower border some two inches from the vaginal roof. It was easily peeled off, a sponge soaked in perchloride of iron following it up. There was very little bleeding. The clots were removed from the cavity, its walls were touched with perchloride, and the operation ended. Much exhaustion followed the operation. The child weighed eight pounds seven and a half ounces, and appeared mature. The placenta was three-lobed, but was destroyed before a careful examination could be made. The after-treatment consisted in washing out the cavity antiseptically. The opening healed in three months. Severe pain in the side lasted for nearly two years after the operation. She was seen in August, 1883, in excellent health, had no pain except after great fatigue; had menstruated normally for six months. The child was healthy, the largest, and a great deal the heaviest, of the family.

[1] Medical Times, May 31st.

THE COURSE OF THE FEVER IN ACUTE CROUPOUS PNEUMONIA.

SILVESTRINI[2] dwells upon the somewhat neglected irregularity of the fever in acute pneumonia. The temperature, he thinks, practically does not, as a rule, adapt itself to the classical three periods of the disease.

There are cases of pneumonia which run their course in three days, others in much more; and the temperature follows in its behavior the various phases of the morbid process. The temperature-curve is irregular even in cases of frank pneumonia following a typical course; if the temperature be taken every two hours, oscillations are noticed which escape observation if the thermometer be only used twice a day. The author records cases in which objective examination and consideration of the thermic curve showed that rise of temperature always coincided with the appearance of a new pneumonic nucleus, and diminution or cessation of fever with the appearance of the signs of hepatization. At this moment, when the exudation coagulates, a compression is produced between alveolus and alveolus, and arrest of the blood and lymphatic circulation, and hence absorption of the pyrogenic products of inflammation is prevented. Fever only accompanies the period of exudation, during which the absorption of the pyrogenic products is facilitated; every elevation of temperature corresponds to a new invasion of the process, the pneumonia being considered as the union of so many pneumonic processes, which succeed one another with greater or less rapidity in different cases; and this succession of accesses goes *pari passu* with the oscillations of the thermic curve. The duration of the morbid process is short, the succession of anatomo-pathological periods rapid; but the nature of the process is to diffuse itself in other territories, where the same phenomena are developed, capable of producing the same manifestations. If the invasion take place quickly, there will be almost continuous fever; if slowly and interruptedly, the fever will have a more or less regularly intermittent type. If the pneumonia invade one tract only of the lung, and be arrested there, it will give rise to symptoms only lasting one day or two; if the process invade gradually all parts of a lung, there will be fever of long duration. The diffusion of the morbid process is by the bronchi, and not by lymphatic absorption or contiguity. If the diffusion took place by contiguity, those cases in which the process invades irregularly various zones of the lung could not be explained.

BIPOLAR VERSION IN PLACENTA PRÆVIA.

THE *Medical Times and Gazette* (May 24th) quotes with approval as being in agreement with the practice of some of the best English accoucheurs an article in a recent number of the *Zeitschrift für Geburtshülfe und Gynäcologie*, by Dr. C. Behm, of Berlin. It is based on cases observed in the clinic of Professor Gusserow. The author's experience of placenta prævia consists of fifty-three cases, of which the first thirteen were treated by plugging, rupture of the membranes, and version by the old "internal" method. They comprised five cases, in which the placenta was completely prævia; five partial or "lateral" (to use Dr. Behm's word), and three marginal. Of the thirteen, four mothers

[2] Revista Clinica, November, 1883. London Medical Record, February 15, 1884.

died, that is 30.8 per cent., and of the nine who survived, four suffered from febrile illness during the lying-in. The children were fourteen in number, and ten of them died during or soon after birth, a mortality of 71.4 per cent. These percentages Dr. Behm compares with the statistical statements of other writers, and finds that they represent about an average mortality. The principle of treatment adopted by Dr. Behm, in his latter forty cases, was that of bimanual version, after the method of Braxton Hicks, as early as possible, one foot being brought down through the os, and the labor then left to be gradually completed by the natural efforts, the pressure of the breech on the cervix being trusted to restrain hæmorrhage. The result was, that he lost not a single mother out of the forty. The infantile mortality was 77.5 per cent. Hofmeier, out of thirty-seven cases, treated in a similar way, only lost one mother, but of the children sixty-three per cent. In Dr. Behm's series of forty cases, he performed early bipolar version thirty times. In seven the membranes ruptured early, so that version had to be longer delayed, and three were cases of head presentation, in which delivery was left to Nature. The advantages of this plan of treatment, Dr. Behm points out, are these: (1.) The necessary intervention is effected early, as soon as the os will admit two fingers, before the mother has lost much blood, or become exhausted. (2.) The breech, drawn down upon the os by slight pressure, forms a perfect tampon. (3.) As delivery is effected slowly, shock is avoided. As to the technique of the operation, Dr. Behm remarks that two fingers should be introduced through the os. If the cervix will not admit two fingers, it should be dilated with water bags. If the presentation of the placenta be complete, it will be found that it separates most easily on the side nearest to its edge; if the edge cannot be reached, it is best to perforate the placenta. After the breech has been brought into the os uteri, expulsion is best left to Nature. The accoucheur's motto in these cases should be, "haste with patience" (*Eile mit Weile*), haste in turning, patience in extraction.

REPORTED MORTALITY FOR THE WEEK ENDING JUNE 14, 1884.

Deaths reported 1991 (no reports from Philadelphia, St. Louis, Buffalo, District of Columbia, and Providence): under five years of age, 823; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 403, consumption 282, lung diseases 189, diarrhœal diseases 129, diphtheria and croup 85, measles 51, scarlet fever 35, typhoid fever 25, whooping-cough 20, malarial fevers 19, cerebro-spinal meningitis 12, small-pox

nine, puerperal fever nine, erysipelas seven, typhus fever two. From *scarlet fever*, Chicago 11, New York 10, Boston five, Baltimore and Milwaukee two each, Brooklyn, Cincinnati, Pittsburg, Woburn, and Chelsea one each. From *typhoid fever*, New York, seven, Chicago four, Baltimore three, Cincinnati, New Orleans, Spencer, and Charleston two each, Brooklyn, Pittsburg, and Lynn one each. From *whooping-cough*, New York five, Brooklyn, Baltimore and New Orleans three each, Chicago, Boston, and Somerville two each. From *malarial fevers*, New Orleans six, Brooklyn four, New York three, Chicago and Charleston two each, Baltimore and Cincinnati one each. From *cerebro-spinal meningitis*, New York three, Chicago two, Cincinnati, New Orleans, Nashville, Lowell, Worcester, Fall River, and Chicopee one each. From *small-pox*, New Orleans seven, Pittsburg and Nashville one each. From *puerperal fever*, New York, Brooklyn, Chicago, and Cincinnati two each, Boston one. From *erysipelas*, New York, Brooklyn, and New Haven two each, New Orleans one. From *typhus fever*, New York and Chicago one each.

One case of small-pox was reported in Cincinnati; scarlet fever 37, diphtheria 20, typhoid fever seven, and measles three in Boston; scarlet fever 24 and diphtheria seven in Milwaukee.

In 99 cities and towns in Massachusetts, with an estimated population of 1,343,037 (estimated population of the State 1,955,104), the total death-rate for the week was 14.40 against 16.31 and 16.50 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending May 31st, the death-rate was 20. Deaths reported 3354: acute diseases of the respiratory organs (London) 261, measles 150, whooping-cough 133, scarlet fever 65, diarrhœa 44, small-pox (London 36, Liverpool three, Sheffield, Sunderland, and Cardiff one each) 42, fever 39, diphtheria 27. The death-rates ranged from 11.3 in Derby to 29.3 in Wolverhampton; Birkenhead 17.2; Nottingham 17.3; London 19.2; Birmingham 20.6; Leeds 20.6; Sunderland 22; Liverpool 22.4; Manchester 23; Leicester 23.6; Sheffield 24.1. In Edinburgh 23.1; Glasgow 24; Dublin 22.3.

For the week ending May 31st, in the Swiss towns, there were 29 deaths from consumption, lung diseases 20, typhoid fever 18, diarrhœal diseases 12, diphtheria and croup four, whooping-cough two, erysipelas two. The death-rates were, at Geneva 19.4; Zurich 17.7; Basle 13.2; Berne 25.6.

The meteorological record for the week ending June 14th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps: —

Date. June, 1884.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM JUNE 14, 1884, TO JUNE 20, 1884.

HAPPERSETT, J. C. G., major and surgeon. Granted leave of absence for four months. Paragraph 5, S. O. 141, A. G. O., June 18, 1884.

CHANGES IN DEPARTMENT OF TEXAS.

PORTER, J. Y., captain and assistant surgeon. From Fort Ringgold, Texas, to Fort Brown, Texas, as post surgeon.

MADDOX, T. J. C., first lieutenant and assistant surgeon. From Fort Clark, Texas, to Fort Ringgold, Texas, as post surgeon.

BLACK, C. S., first lieutenant and assistant surgeon. From Fort Concho, Texas, to Fort Clark, Texas.

S. O. 73, headquarters Department of Texas, June 9, 1884.

LIST OF OFFICIAL CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING JUNE 21, 1884.

KNIGHT, J. S., surgeon, ordered before Retiring Board.

HERNDON, C. G., passed assistant surgeon, detached from the Albatross, ordered to attend officers of Navy and Marine Corps in Washington.

FLINT, J. M., surgeon, detached from Smithsonian Institute, ordered to Fish Commission steamer Albatross.

LEACH, P., assistant surgeon, ordered for examination preliminary to promotion.

GARDENER, J. E., passed assistant surgeon, detached from U. S. S. Lancaster, ordered to U. S. S. Powhatan.

BOYD, J. C., passed assistant surgeon, detached from U. S. S. Lancaster, ordered to U. S. S. Powhatan.
